THE WATERHOUSE-FRIDERICHSEN SYNDROME

MAJOR VINCENT C. D'AGATI, M.C., A.U.S., AND MAJOR BRUNO A. MARANGONI, M.C., A.U.S.

THE Waterhouse-Friderichsen syndrome is a clinical entity first described in 1911 by Waterhouse¹ in an eight-month-old child. In 1918, Friderichsen² reviewed the literature and described a similar case with a fulminating course, characterized clinically by stupor, cyanosis, pallor, vomiting and a rapidly spreading purpuric eruption, and at autopsy by massive bilateral adrenal hemorrhages. This syndrome is associated with a bacteremia, the etiologic agent in the majority of cases being the meningococcus. Although the pneumococcus, hemolytic streptococcus and staphylococcus have also been incultured, considerable doubt has been cast on the role of any of these organisms as the offending agent.

Most of the cases have occurred in children, but with the recent and widespread increase in meningococcal infections there have been many additional reports of this syndrome in adults.³⁻⁵ Although in the majority of reported cases the patients succumbed within twenty-four hours of onset, a few survived for as long as forty-eight hours. Recently, 2 cases with survival periods of eighty and eighty-eight hours both proved by autopsy, were described.⁶ Evidently this syndrome is not universally fatal, for there are 6 cases of recovery on record.⁷⁻¹²

We have observed 6 cases of the Waterhouse-Friderichsen syndrome — 5 with a fatal outcome and 1 with recovery — in a large series of meningococcal infections encountered at a station hospital. This presentation is an attempt to correlate the clinical, pathological and laboratory data obtained in these cases. The literature on recovery from this syndrome will be reviewed, and an additional case will be presented in detail.

CLINICAL FEATURES

The clinical manifestations of the Waterhouse-Friderichsen syndrome have not been generally recognized. The paucity of clinical investigations is probably due to several factors, namely, failure in diagnosis, a fulminating course and the scarcity of cases seen by any one observer. The increasing prevalence of meningococcal infections has focused the attention of clinicians on this syndrome, and

it is reasonable to suppose that it will be recognized more frequently in the future. The clinical features of our 5 fatal cases have been so similar as to warrant detailed discussion. The case with recovery varied slightly from the others and will be described separately.

The prodromal symptoms were similar to those encountered in any respiratory infection, consisting of headache, chilly sensations, muscular pains and malaise. The onset of the bacteremia was sudden and dramatic. The most striking features were the profound shock and the petechial eruption, which in the course of a few hours became purpuric. The skin lesions varied in size from small petechiae several millimeters in diameter to large, violaceous purpuric areas widely distributed over the body. They did not disappear on digital pressure, and in some cases necrosis and sloughing followed in the later stages. The patients were apprehensive and restless. Despite an initial temporary delirium, mental lucidity was maintained throughout. There was pallor of the face and trunk. In addition, a nephritic type of facial edema was present. The lips and extremities were cold and cyanotic. Perspiration was profuse. Vomiting, persistent diarrhea and abdominal pain were frequent complaints.

The temperature was moderately elevated early in the disease, ranging from 100 to 102°F., but within twenty-four to thirty-six hours it dropped to normal and remained at normal or slightly sub-normal levels until death. The pulse rate was accelerated throughout. The respirations were rapid and shallow during the initial shock, but with recovery from it they became slower and deeper. Twenty-four hours before death they rose sharply, averaging 48 per minute. Of particular interest is the fact that respirations ceased a few minutes prior to the failure of heart function.

Early in the disease, hypotensive blood-pressure levels were encountered. Frequently diastolic readings were unobtainable. With recovery from the initial shock the blood pressure rose to quasi-normal levels.

Soon after the onset, a few scattered moist rales were audible at both lung bases. This condition

gradually progressed until numerous coarse, bubbling rales could be heard over both lung fields. With the appearance of frank pulmonary edema terminally, the patient lapsed into coma and died shortly thereafter.

Remarkably little attention has heretofore been paid to the initial anuria, which was a constant finding in these cases. The anuria persisted for twenty-four to thirty-six hours and was replaced by a severe oliguria. At no time was adequate renal

nonprotein nitrogen level. In 3 cases, this finding was observed within twelve hours of onset and ranged between 52 and 64 mg. per 100 cc.; in 1 case, the blood was examined terminally. In all cases, the nonprotein nitrogen rose steadily, 96.9 mg. being the highest recorded level. Associated with this change was an early elevation of the blood creatinin, the concentrations varying between 5.4 and 9.0 mg. It is worthy of comment that the elevation of the nonprotein nitrogen was moderate, whereas that of

function re-established, despite recovery from shock, evidenced by normal blood-pressure readings, the improved character of the pulse and the improved clinical appearance of the patient.

LABORATORY DATA

No significant biochemical studies of the Waterhouse-Friderichsen syndrome have hitherto been reported. We have therefore devoted some attention to the study of electrolyte balance and renal function. The data in all 6 cases are summarized in Table 1.

The blood chemical changes were investigated in 4 cases. All the patients exhibited elevation of the

creatinin was marked. The icteric index showed a slight elevation to 13.7 in one of the fatal cases (Case 3). In contrast, the patient in Case 6, who recovered, had an icteric index of 6.0. In 3 cases (Cases 3, 5 and 6), the blood chloride levels were within normal limits.

In 2 patients (Cases 3 and 6), sodium and potassium determinations were done. Both showed slight sodium retention — 403 and 345 mg., respectively (normal, 315 to 340 mg.). In the case with a fatal outcome, the sodium continued to rise; in the recovered case, on the other hand, it dropped to a subnormal concentration. In the former the potassium was low, — 10 mg. (normal, 16 to 22 mg.), — where-

as in the latter it was normal. With recovery, however, the blood potassium also fell to a subnormal level.

A marked leukocytosis was observed in 5 cases, a blood-cell count being obtained in the other case. The white-cell count varied between 33,000 and 73,150, with a substantial increase in neutrophils. Although in some cases the initial counts were only moderately elevated, they invariably exhibited extreme leukocytosis during the subsequent twenty-four hours.

Urinalysis was done in all cases from which specimens could be obtained. Fixation of the specific gravity, and varying degrees of albuminuria, were noted. Interestingly enough, Case 4 demonstrated, in addition, a microscopic hematuria and cylindruria.

Neisseria intracellularis was cultured from the

in detail. Since these observations have an obvious bearing on the subject of this paper, the previous studies have been extended to include the remaining cases of the syndrome. Post-mortem examinations were performed in all the fatal cases (Table, 2). In evaluating these findings, it must be stressed that there is a vast difference in the morphologic structure of the liver, kidney and heart in short-lived cases as compared with that of those with longer survival periods.

The lungs revealed pleural effusion and pulmonary edema.

The adrenal glands were enlarged, varying in weight between 11 and 26 gm. Hemorrhagic areas were present bilaterally in the cortex and medulla. The shortest-lived cases (Cases 1, 2 and 3) showed the most extensive interstitial hemorrhages. It is

TABLE 2. Pathologic Features.

CASE No	LUNGS	HEART*	ASCITIC FLUID cc	LIVER	KIDNEYS	ADRENAL GLANDS
1	Pleural effusion (500 cc), pulmonary edema	Weight 300 gm; cloudy swelling of muscle fibers	None	Weight 1690 gm, mild hepatitis of central zone	Weight, 160 gm left and 160 gm right; normal histologically	Weight, 16 gm, severe bilateral hemorrhages
2	Pleural effusion (scant), pulmonary edema	Weight 370 gm, cloudy swelling of muscle fibers	None	Weight 1960 gm, mild hepatitis of central zone	Weight, 140 gm left and 135 gm right, normal histologically	Weight, 11 gm, severe bilateral hemorrhages
3	Pleural effusion (250 cc right, and 100 cc left), pulmonary edema	Weight 350 gm, pericardial effusion (100 cc), cloudy swelling and fragmentation of muscle fibers and interstitial edema	None	Weight 1950 gm, early necrosis of central zone	Weight, 145 gm left and 160 gm right, increased cellularity and avascularity of glomerular tufts, cloudy swelling of convoluted tubular epithelium, and albuminour casts	Weight 26 gm, moderate bilateral hemorrhages
4	Pleural effusion (200 cc right and 200 cc left), pulmonary edema	Weight 410 gm, pericardial effusion (50 cc), same as Case 3 but severer	1000	Weight 2035 gm, dissociation of liver cords in central zone and severe necrobiosis of hepatic cells in central zone and midzone	Weight, 170 gm left and 185 gm right, histologically same as Case 3 but severer.	Weight, 15 gm, moderate bilateral hemorrhages
5	Pleural effusion (500 cc right and 75 cc left), pulmonary edema	Weight 590 gm, pericardial effusion (75 cc), same as Case 3 but severer	500	Weight 2790 gm; dissociation of liver cords, severe necrobiosis in central zone and midzone and early necrosis of hepatic cells in peripheral zone	Weight, 280 gm left and 240 gm right, histologically same as Case 3 but severer	Weight, 20 gm, moderate bilateral hemorrhages

*All cases except Case 1 revealed dilatation of the right auricle and ventricle

blood of each case. Despite grossly and microscopically negative spinal fluids, the cultures in 3 cases were positive.

PATHOLOGICAL FINDINGS

Characteristic morphologic changes do exist in the Waterhouse-Friderichsen syndrome. Failure to recognize these structural variations may be attributed to the fact that such changes are progressive and become well defined only in those cases that have a prolonged clinical course. In reviewing the literature, we were impressed by the reports of the unusual brevity of this syndrome, the majority of patients succumbing within twenty-four hours, with an occasional survival period of forty-eight hours. In a previous publication we⁶ reported 2 proved cases with prolonged survival periods and discussed the characteristic pathological features

evident from these observations that the length of survival is determined by the severity of destruction of adrenal tissues.

The livers were enlarged, weighing between 1950 and 2790 gm, except for that in Case 1, which weighed 1690 gm. The largest livers were seen in Cases 4 and 5, which had the longest survival periods. The microscopic changes varied in direct proportion to the survival time. In the shortest-lived cases (Cases 1 and 2), the sole finding was a mild hepatitis of the central zone. In Case 3, in which the patient survived for forty hours, an early necrosis of the central zone was present. In Case 4, with a survival time of eighty hours, there was dissociation of the liver cords of the central zone, with severe necrobiosis of the hepatic cells, midzonal necrobiosis and vacuolization of the hepatic cells, and a normal peripheral zone. However, Case 5, with a survival

period of eighty-eight hours, revealed similar although severer central and midzonal changes than did Case 4 and, in addition, early necrobiosis of the cells in the peripheral zone.

The kidneys were enlarged in only 2 cases (Cases 4 and 5), in which together they weighed 355 and 520 gm., respectively. The histologic architecture in Cases 1 and 2 was normal. In Cases 3, 4 and 5, with clinical courses of forty, eighty and eighty-eight hours, respectively, the microscopic features, although similar to one another, again were severest in the cases with the longest survivals. These consisted of increased cellularity and avascularity of the glomerular tufts, cloudy swelling of the proximal convoluted tubular epithelium and albuminous deposits in the tubular lumens. It therefore seems justifiable to conclude that significant renal changes are found only in those cases with prolonged survival periods.

The heart was grossly abnormal in 4 of the 5 fatal cases (Cases 2, 3, 4 and 5). These abnormalities consisted of cardiac hypertrophy, with the weight varying between 350 and 590 gm., and with marked dilatation of the right auricle and right ventricle. Pericardial effusion occurred in Cases 3, 4 and 5. No noteworthy gross changes were present in Case 1, in which the patient survived for two hours. The myocardium in all 5 cases revealed microscopic findings of a nonspecific character and were similar to those found in other infectious diseases and septicemias. Cloudy swelling was observed in all cases, but in addition, Cases 3, 4 and 5 disclosed fragmentation of the muscle fibers and interstitial edema. These degenerative changes were most advanced in the cases with the longest clinical courses.

The lungs, liver, spleen, kidneys and brain exhibited severe congestion. Petechiae were distributed over the serous membranes, gastrointestinal tract and heart — subendocardium, epicardium and papillary muscles. Pleural, pericardial and peritoneal serous effusions were found that clotted spontaneously. In only 1 case (Case 3) was a purulent inflammation of the meninges present.

DIAGNOSIS

It is appropriate at this point to consider the diagnostic problem posed by the Waterhouse-Friderichsen syndrome. Since the incidence of this entity is constantly rising, the necessity for uniform criteria can hardly be disputed. From a survey of the foregoing material, there have been gathered clinical and laboratory data on which a diagnosis of this syndrome can be based. The following points are regarded to be of diagnostic significance: petechial eruption rapidly becoming purpuric; severe shock; facial edema; anuria of twenty-four to thirty-six hours' duration, followed by marked oliguria; urinalysis showing fixation of the specific gravity, albuminuria, hematuria or cylindruria; marked

leukocytosis; isolation of the meningococcus by culture and, in some cases, by peripheral blood smear; renal failure, as evidenced by elevation of the blood nonprotein nitrogen and creatinin; and elevation of the blood sodium and diminution of the blood potassium.

A diagnosis of this syndrome cannot be based solely on any isolated factor mentioned above. On the basis of these studies it is concluded that the clinical signs per se are sufficient to warrant the diagnosis in acute, fulminating cases. With a more prolonged course, however, additional factors involving the alterations in blood chemistry, as well as the isolation of the meningococcus, must be consistently present to confirm the diagnosis.

TREATMENT

The therapeutic approach in the Waterhouse-Friderichsen syndrome resolves itself into the treatment of shock, toxemia and bacteremia and the administration of adrenocortical hormone substitution therapy.

Shock is combated in the usual manner. The employment of heat and stimulants and the antishock position are advocated. Parenteral fluids in quantities of 3000 to 4000 cc. should be given cautiously over a twenty-four-hour period. The intravenous administration of 500 cc. of plasma, repeated in twelve hours, is recommended because of its osmotic effect, mirrored in a noticeable elevation of the blood pressure. The use of epinephrin, in our experience, is of questionable value.

Toxemia is the gravest problem encountered in this entity, and the pathologic changes are directly attributable to it. Although at the present time there is no clear evidence that serotherapy is of value in meningococcal infections, it seems advisable to administer antimeningococcus serum in adequate amounts — 60,000 to 120,000 units — intravenously within the first twenty-four hours.

The control of meningococcemia has been made possible by the advent of chemotherapy. Of all the sulfonamide drugs, sulfadiazine is the derivative of choice. The necessity for massive doses of this drug, parenterally and orally, is apparent when one considers the overwhelming character of the bacteremia. The initial dose of sulfadiazine in this series was 5 gm. intravenously and 8 gm. orally. This was followed by large oral doses until a total of 25 to 30 gm. had been given within the first twenty-four hours. The blood-sulfadiazine concentration was used as a guide for determining the size and frequency of subsequent doses. The optimal blood level was considered to be 15 to 20 mg. per 100 cc.

The rationale of adrenocortical hormone substitution therapy in the Waterhouse-Friderichsen syndrome has been directed toward combating adrenal dysfunction resulting from the extensive hemorrhages and necrosis. The hope that this form of organotherapy would succeed in tiding the patient

over his critical period has met with disappointment. Experience indicates that its value is questionable. No resultant clinical improvement could be detected in the 4 cases in which it was used. Nevertheless, it may have contributed to the prolongation of the clinical course.

RECOVERY

Only 6 cases of the Waterhouse-Friderichsen syndrome with recovery have been reported in the literature.⁷⁻¹² A review of these cases failed to reveal any uniform criteria for diagnosis. The meningococcus was the etiologic agent in 5 of these cases. The pneumococcus was isolated from the case reported by Bickel.⁷

The diagnosis of recovery in this entity must necessarily be based solely on the clinical findings and laboratory data, because no pathologic evidence is available. It must be emphasized that fulminating meningococcemia associated with shock may simulate the Waterhouse-Friderichsen syndrome, but in the former autopsy fails to disclose any adrenal hemorrhages. From our observations, it is concluded that the important clinical differentiation of these two types is that in meningococcemia with shock no anuria and oliguria or retention of nitrogenous products in the blood occurs, whereas they are consistently present in the Waterhouse-Friderichsen syndrome. The cases of Carey,⁸ Peabody¹⁰ and Rucks and Hobson¹¹ showed many features that are found in the above criteria for diagnosis, particularly the purpuric manifestations, shock, anuria and oliguria, leukocytosis and elevation of the blood nonprotein nitrogen level.

In a previous publication, we⁶ maintained that recovery was unlikely because of the basic morphologic changes found at post-mortem examination in protracted cases. In retrospect, this statement should be modified, because a case with recovery has since been observed. It is believed that the bacteremia, toxemia and resulting adrenal hemorrhages are quantitative; that they may be lethal or sublethal can hardly be questioned. It is not inconceivable, therefore, that this triad with its train of pathologic changes may be mild to moderate and fully compatible with recovery.

The following case is presented in detail as an example of recovery from the Waterhouse-Friderichsen syndrome. Interestingly enough, the clinical course and laboratory findings were not unlike those in the case reported by Peabody.¹⁰

CASE REPORT

An 18-year-old soldier was admitted to a station hospital complaining of headaches, nausea and pains in the neck and back. On admission the temperature was 102°F., the pulse 92, and the respirations 36. Physical examination was essentially negative except for coryza and a red, injected pharynx. Three hours later the patient became delirious and irrational. He vomited bile-stained fluid and passed frequent, involuntary watery stools. Petchiae were first observed at that time. The blood pressure was 60/0, and the pulse 150.

A lumbar puncture revealed clear spinal fluid under normal pressure, which was negative on laboratory examination. A white-cell count taken shortly after admission was 17,050, with 80 per cent neutrophils. A diagnosis of meningococcemia was made and treatment with 8 gm. of sulfadiazine by Levin tube was instituted. Subsequent sulfadiazine therapy consisted of 3 gm. every 3 hours. Parenteral fluids and 1 cc. of metrazol were administered intravenously.

The patient lapsed into a stuporous state 8 hours after entry. The temperature remained at 102°F. Examination disclosed slight facial edema. Numerous violaceous, petechial and purpuric areas were widely distributed over the trunk and extremities. Nuchal rigidity was absent. No abnormal neurologic signs could be elicited. The blood pressure was 68/0. A second white-cell count was 49,550, with 83 per cent neutrophils. The blood-sulfadiazine level was 13.8 mg. per 100 cc., and the blood chlorides 396 mg. Urinalysis could not be done because of complete anuria since admission. Blood and spinal-fluid cultures were positive for *Neisseria intracellulularis* (Type I). A diagnosis of severe meningococcemia complicated by adrenal hemorrhages (Waterhouse-Friderichsen syndrome) was made. Intensive sulfadiazine therapy was continued orally, and 5.5 gm. of sodium sulfadiazine dissolved in sterile distilled water was administered intravenously. In addition, 30,000 units of meningococcus antitoxin with 1 cc. of epinephrin and 5 cc. of adrenocortical hormone was given by intravenous drip and repeated 6 hours later.

On the 2nd hospital day, 28 hours following admission, the patient was clinically improved. He appeared rational and the blood pressure rose to 72/40. The temperature was 99.4°F., the pulse 70, and the respirations 18. Despite intensive administration of fluids, the anuria persisted. The urinary bladder could not be palpated. The patient continued to vomit and complained bitterly of diffuse abdominal pain and diarrhea.

He received 27 gm. of sulfadiazine during the first 24 hours of therapy. The white-cell count fell to 23,950, with 96 per cent neutrophils. Complete blood chemical studies were done and were reported as follows: nonprotein nitrogen, 64 mg.; creatinin, 5.4 mg.; sugar, 101 mg.; chloride, 412 mg.; sodium, 345 mg.; potassium, 16.9 mg.; and icterus index, 6.0. The blood pressure rose to 80/60.

Vigorous sulfonamide therapy was continued, and a dosage schedule of 3 gm., alternated with 2 gm., administered orally every 3 hours was initiated. A blood sulfadiazine level of 14.4 mg. per 100 cc. was reported at that time. Renal function was re-established 41 hours after admission, at which time the patient spontaneously voided 540 cc. of dark-amber urine, which had a specific gravity of 1.010 and showed a moderate trace of albumin and a few white cells.

On the 3rd day, facial edema and asthenia were still present. The temperature fluctuated between 100 and 102°F. The blood pressure continued to climb, reaching 100/78. Blood chemical determinations were repeated, with the following results: nonprotein nitrogen, 70 mg.; creatinin, 4.7 mg.; sodium, 324 mg.; and potassium, 19.8 mg. The blood sulfadiazine was maintained at a satisfactory concentration of 16.6 mg. The total fluid intake was 4120 cc., and the urinary output 1100 cc. The sulfadiazine was then reduced to 2-gm. doses, alternated with 1 gm., every 4 hours. Throughout the remainder of the first week, there was fixation of the urinary specific gravity at 1.010.

Definite improvement was observed on the 4th day. The asthenia was considerably lessened. The first laboratory findings to confirm the clinical impression of recovery were a fall in the creatinin level to 3.6 mg. and one in the sodium level to 271 mg., with a concomitant fall in the potassium level to 12.8 mg. The nonprotein nitrogen was reported as 78 mg., a slight rise over the previous level. The blood chloride continued to increase, having attained a level of 479 mg. The white-cell count was 24,750, with 96 per cent neutrophils. The blood-sulfadiazine level was 19.5 mg., representing a slight increase over the previous reading. The fluid intake and urinary output were 3840 cc. and 2640 cc., respectively.

On the 6th day, the facial edema had completely disappeared, the purpuric lesions had faded and the temperature returned to normal for the first time. The white-cell count was 14,000, with 80 per cent neutrophils. The nonprotein nitrogen dropped to a level of 50 mg., and the creatinin to 3.2 mg. The sulfadiazine was discontinued.

The clinical course from that time on was one of progressive improvement. The sole complicating feature was a

period of eighty-eight hours, revealed similar although severer central and midzonal changes than did Case 4 and, in addition, early necrobiosis of the cells in the peripheral zone.

The kidneys were enlarged in only 2 cases (Cases 4 and 5), in which together they weighed 355 and 520 gm., respectively. The histologic architecture in Cases 1 and 2 was normal. In Cases 3, 4 and 5, with clinical courses of forty, eighty and eighty-eight hours, respectively, the microscopic features, although similar to one another, again were severest in the cases with the longest survivals. These consisted of increased cellularity and avascularity of the glomerular tufts, cloudy swelling of the proximal convoluted tubular epithelium and albuminous deposits in the tubular lumens. It therefore seems justifiable to conclude that significant renal changes are found only in those cases with prolonged survival periods.

The heart was grossly abnormal in 4 of the 5 fatal cases (Cases 2, 3, 4 and 5). These abnormalities consisted of cardiac hypertrophy, with the weight varying between 350 and 590 gm., and with marked dilatation of the right auricle and right ventricle. Pericardial effusion occurred in Cases 3, 4 and 5. No noteworthy gross changes were present in Case 1, in which the patient survived for two hours. The myocardium in all 5 cases revealed microscopic findings of a nonspecific character and were similar to those found in other infectious diseases and septicemias. Cloudy swelling was observed in all cases, but in addition, Cases 3, 4 and 5 disclosed fragmentation of the muscle fibers and interstitial edema. These degenerative changes were most advanced in the cases with the longest clinical courses.

The lungs, liver, spleen, kidneys and brain exhibited severe congestion. Petechiae were distributed over the serous membranes, gastrointestinal tract and heart — subendocardium, epicardium and papillary muscles. Pleural, pericardial and peritoneal serous effusions were found that clotted spontaneously. In only 1 case (Case 3) was a purulent inflammation of the meninges present.

DIAGNOSIS

It is appropriate at this point to consider the diagnostic problem posed by the Waterhouse-Friderichsen syndrome. Since the incidence of this entity is constantly rising, the necessity for uniform criteria can hardly be disputed. From a survey of the foregoing material, there have been gathered clinical and laboratory data on which a diagnosis of this syndrome can be based. The following points are regarded to be of diagnostic significance: petechial eruption rapidly becoming purpuric; severe shock; facial edema; anuria of twenty-four to thirty-six hours' duration, followed by marked oliguria; urinalysis showing fixation of the specific gravity, albuminuria, hematuria or cylindruria; marked

leukocytosis; isolation of the meningococcus by culture and, in some cases, by peripheral blood smear; renal failure, as evidenced by elevation of the blood nonprotein nitrogen and creatinin; and elevation of the blood sodium and diminution of the blood potassium.

A diagnosis of this syndrome cannot be based solely on any isolated factor mentioned above. On the basis of these studies it is concluded that the clinical signs per se are sufficient to warrant the diagnosis in acute, fulminating cases. With a more prolonged course, however, additional factors involving the alterations in blood chemistry, as well as the isolation of the meningococcus, must be consistently present to confirm the diagnosis.

TREATMENT

The therapeutic approach in the Waterhouse-Friderichsen syndrome resolves itself into the treatment of shock, toxemia and bacteremia and the administration of adrenocortical hormone substitution therapy.

Shock is combated in the usual manner. The employment of heat and stimulants and the antishock position are advocated. Parenteral fluids in quantities of 3000 to 4000 cc. should be given cautiously over a twenty-four-hour period. The intravenous administration of 500 cc. of plasma, repeated in twelve hours, is recommended because of its osmotic effect, mirrored in a noticeable elevation of the blood pressure. The use of epinephrin, in our experience, is of questionable value.

Toxemia is the gravest problem encountered in this entity, and the pathologic changes are directly attributable to it. Although at the present time there is no clear evidence that serotherapy is of value in meningococcal infections, it seems advisable to administer antimeningococcus serum in adequate amounts — 60,000 to 120,000 units — intravenously within the first twenty-four hours.

The control of meningococcemia has been made possible by the advent of chemotherapy. Of all the sulfonamide drugs, sulfadiazine is the derivative of choice. The necessity for massive doses of this drug, parenterally and orally, is apparent when one considers the overwhelming character of the bacteremia. The initial dose of sulfadiazine in this series was 5 gm. intravenously and 8 gm. orally. This was followed by large oral doses until a total of 25 to 30 gm. had been given within the first twenty-four hours. The blood-sulfadiazine concentration was used as a guide for determining the size and frequency of subsequent doses. The optimal blood level was considered to be 15 to 20 mg. per 100 cc.

The rationale of adrenocortical hormone substitution therapy in the Waterhouse-Friderichsen syndrome has been directed toward combating adrenal dysfunction resulting from the extensive hemorrhages and necrosis. The hope that this form of organotherapy would succeed in tiding the patient

may well account for the degenerative changes found in the liver, kidneys and heart.

SUMMARY AND CONCLUSIONS

A report is made of 6 cases of the Waterhouse-Friderichsen syndrome. Criteria for diagnosis based on an analysis of these cases are presented. A case of recovery is discussed in detail, and the literature on recovery in this syndrome is reviewed.

The following conclusions are based on a study of these cases:

The clinical features are fairly constant. The significance of the renal failure as evidenced by the initial anuria followed by oliguria has heretofore not been fully appreciated.

The pathologic findings are uniform but vary in degree. All cases have macroscopic bilateral adrenal hemorrhages. Microscopically the changes in the heart, liver and kidneys are not conspicuous in the short-lived cases but are pronounced in those cases with relatively long clinical courses.

The roles of bacteremia and shock in pathogenesis have been overemphasized. Death in all cases is probably the effect of the overwhelming tox-

emia, which in the short-lived cases results in profound shock and in those with relatively long survival periods leads to hepatorenal failure.

TRANSITORY LUNG INFILTRATIONS ACCOMPANIED BY EOSINOPHILIA

Report of a Case

CAPTAIN HENRY MILLER, M.C., A.U.S.

THE clinical aspects of any disease may be said to comprise a group of features that in the aggregate tend to classify it as a clinical entity. Some diseases have certain pathognomonic features that identify them immediately, whereas in others the clinical picture is simulated by such a variety of etiologic agents that it is impossible to be certain of the diagnosis except by careful study and the elimination of similar diseases. Such a condition is the syndrome of transient pulmonary infiltrations with blood eosinophilia, first described in 1932 by Loeffler,¹ professor of medicine at the University of Zurich. By 1940, 105 cases had been reported in the literature.² 51 of them by Loeffler.³

The most important criteria for diagnosis are the symptoms and signs of pulmonary disease, the extent and character of pulmonary involvement, the transient character of the pulmonary shadows, eosinophilia, and seasonal and sex variation. These will now be discussed. The symptoms as a rule are few, and the course is mild and invariably benign. The majority of patients do not appear to be acutely ill. Over 25 per cent of Loeffler's cases were discovered accidentally. There is rarely any appreciable rise of temperature. A cough, with or without chest pain and expectoration of frothy, mucoid sputum, may be present. Abnormal physical signs

over the lungs are few, and in general consist of occasional moist rales. Sometimes impairment of the percussion note and changes in breath sounds are elicited. The sedimentation rate is usually increased.

X-ray examination usually reveals a more extensive pulmonary involvement than was suspected from the clinical examination. The characteristic x-ray picture described by Loeffler and also by Breton⁴ consists of abnormal shadows that appear and disappear rapidly, only to reappear in another portion of the lung. The involvement varies in size and position. It occurs most frequently in the lower lung fields but may occur anywhere. It may be small or large, unilateral or bilateral, single or multiple and homogeneous or spotty. A fine, fibrous, star-shaped scar may be left after resolution. Occasionally there is a small pleural effusion, but it is never large enough to warrant thoracentesis. The pulmonary shadows decrease in size and density in three to eight days, and completely disappear within a few more days. Other shadows may appear in different regions of the lungs in rapid succession.

The eosinophilia usually ranges between 15 and 35 per cent, but has in some cases exceeded 60 per cent. It is associated with the lung shadows, but

temporary exhaustion and delirium state that occurred on the 17th day, characterized by depression, auditory and visual hallucinations and a recurrence of the asthenia that lasted for 6 days. The patient made a complete recovery and was discharged to his unit 46 days after hospitalization. Subsequent examinations showed no sequelae, and the patient was able to resume full military duties.

The clinical course in this case was similar to that in the 5 fatal cases, but differed from it in that renal function was restored and an elevated temperature was maintained. The re-establishment of renal function heralded recovery and was the most important prognostic sign. The rise in the non-protein nitrogen and the creatinin occurred early in the course of the illness.

DISCUSSION

Although cognizant of differences of opinion, we are inclined to agree with Martland⁴ and Herbut and Manges¹³ that the meningococcus is the sole etiologic agent in the Waterhouse-Friderichsen syndrome. The evidence that substantiates this claim is the increased prevalence of this syndrome during epidemics of meningitis and the frequent recovery of the meningococcus. This organism has been found in many isolated cases in which the etiology was obscure. The meningococcus was cultured in the 6 cases of the Waterhouse-Friderichsen syndrome encountered in this series. We strongly doubt the primary role ascribed to other microorganisms and support the concept that they represent secondary invaders.¹³

It is now a well-established fact that the meningococcus obtains its initial hold in the nasopharynx, from which it rapidly invades the blood stream. If adrenal hemorrhages occur, the classic picture of the Waterhouse-Friderichsen syndrome results and is manifested by bacteremia, shock and toxemia. Each of these factors forms the basis of a theory that attempts to explain the pathogenesis of this syndrome. It need scarcely be pointed out that the presence of bacterial organisms in the blood cannot per se adequately explain the adrenal hemorrhages and associated clinical evolution, because the Waterhouse-Friderichsen syndrome does not invariably follow every meningococcemia or other bacteremia. A further objection to the bacteremic theory is the failure in these cases to demonstrate pathologic lesions of a focal embolic type. Nor can shock alone explain the ensuing histologic picture. The major criticism of this concept and of the conclusions drawn is that observations were made in all instances on cases with brief clinical courses. Not until studies have been made on cases surviving the initial phase will one be justified in differentiating this early state of shock from the later and more fully developed toxemic state of hepatorenal failure. These studies have shown that the clinical features of shock, such as weakness, pallor, a thready pulse and low blood pressure, although present early in this syndrome, do disappear within six to eight

hours, provided that the patient survives. A terminal fall in blood pressure was observed. Notwithstanding clinical recovery from shock, which in itself was variable in severity and duration, alterations in the blood nonprotein nitrogen and creatinin continued to progress unfavorably. Furthermore, it was impossible to demonstrate hemoglobin concentration, hypochloremia or a fall in blood sodium and a rise in blood potassium, all of which are characteristic of shock. That the morphologic alterations in structure found in shock are strikingly similar to those found in the Waterhouse-Friderichsen syndrome cannot be questioned, but to attribute the pathologic changes in this syndrome to shock despite obvious clinical recovery from this state is untenable. Thus, the preponderance of evidence supports the principle of toxemia as the most important factor in the pathogenesis of the Waterhouse-Friderichsen syndrome. That shock may have been an early but temporarily associated factor in these cases cannot be denied. Rather, the emphasis must be placed on the toxins elaborated by the meningococcus, with its subsequent disorganization of the structure and function of the endothelial cells, and certain types of parenchymal cells. The endothelial cellular damage resulted in hemorrhage into the skin and adrenal glands, extravasation of fluid into the serous cavities and pulmonary edema. The parenchymatous changes, which were degenerative in nature and were found in the liver, kidney and heart, resulted in hepatorenal failure.

In the previous publication, we⁶ showed the existence of two stages in the Waterhouse-Friderichsen syndrome. The first or fulminating stage was characterized by a short course and circulatory collapse. The pathologic changes were cloudy swelling of the myocardium and an early hepatitis associated with adrenal hemorrhages. Death was most readily accounted for by shock subsequent to the overwhelming toxemia. The second or hepatorenal stage was found only in the patients who survived for longer intervals, and its main histologic features were cloudy swelling with fragmentation of the myocardium, adrenal hemorrhages, a severe and widespread necrobiosis of the hepatic cells and cloudy swelling of the renal convoluted tubular epithelium, together with avascularity and increased cellularity of the glomeruli. Death in these cases was attributed to hepatorenal failure.

We believe that adrenal hemorrhages are necessary for the development of the Waterhouse-Friderichsen syndrome, although it is difficult to explain their exact role. Investigators have shown that the adrenal cortex plays an important part in the maintenance of renal function and body resistance to toxic agents. It is therefore suggested that the destruction of adrenocortical tissues by hemorrhage results in a failure of renal function and increased sensitivity to the meningococcal toxin. The latter

late stages of the myelocytic series. There was a distinct increase in the number of eosinophils.

On November 28, radiographic examination of the chest revealed increased hilar markings, with multiple small areas of increased density scattered through both lung fields (Fig. 1). On December 10, the x-ray films revealed resolution of the previously reported process, but an area of infiltration was present in the lower lobe of the right lung (Fig. 2). On Decem-

disease¹⁷ may at times be associated with a hyper-eosinophilia, but in the present case these diseases can be definitely excluded by the clinical course. There was no means of ruling out familial eosinophilia.¹⁸ There is a group of unusual cases with varying symptoms reported as "eosinophilic leu-

on January 9 revealed clear lung fields. X-ray films of the skull and the long bones revealed no abnormalities.

The patient eventually returned to active duty.

DISCUSSION

With regard to the differential diagnosis, it is to be noted that periarteritis nodosa¹⁶ and Hodgkin's

ber of leukocytes is markedly increased, there is a tendency to hemorrhage, and the outcome is uniformly fatal.¹⁹ In 1931, Bass²⁰ reported a case that was diagnosed as eosinophilic leukemia. X-ray examination revealed generalized speckled shadows throughout both lung fields, which suggested miliary

Loeffler found no parallelism between the degree of eosinophilia and the extent of the infiltrations. There appears to be a definite seasonal variation, most cases being found in July and August; furthermore, males are more frequently affected than are females.

The pathology of this disease is unknown, since no clear-cut fatal case has come to autopsy. In 1939, Smith and Alexander⁵ reported a fatal case of so-called "Loeffler's syndrome" in a seven-year-old girl. As brought out in the discussion, the high fever, stormy course, long duration and fatal outcome did not fit into the picture of a true Loeffler's syndrome. In addition, none of five nationally known pathologists could agree on the diagnosis. Terminal leukemia was granted by one and questioned by the other four.

The etiology of the disease is also uncertain. Most authorities describe the syndrome as an allergic response of the pulmonary tissue that may be induced by various allergens. Loeffler recognized the probable presence of multiple etiologic factors. Leitner⁶ associated the condition with pulmonary tuberculosis. Wild and Loertscher⁷ reported 2 cases of the syndrome in children infected with *Ascaris lumbricoides* and explained the pulmonary shadows as due to the passage of the larvae through the lungs. Engel⁸ described a similar clinical picture of transient pulmonary infiltration and blood eosinophilia in himself and a friend, and attributed the condition to hypersensitivity to the pollen of the privet plant. In 1937, Meyer⁹ reported 8 cases, including one that developed sudden rhinitis, conjunctivitis and edema of the face, accompanied by eosinophilia and lung infiltration. All these manifestations disappeared with calcium therapy and removal of contact to a pollen to which the patient gave a strongly positive reaction. Since then, other investigators have reported transient lung shadows in asthmatic patients and have decided that an allergic process is probably responsible for the entire picture. Although asthma is the most frequently associated allergic manifestation, other forms of allergy have been noted.

Stefano¹⁰ reported a case of bronchial asthma in which transient areas of pulmonary infiltrations demonstrable by x-ray were associated with amebas in the sputum. Both the asthma and the amebas disappeared after emetine therapy. Hoff and Hicks¹¹ have also reported a case of Loeffler's disease associated with amebiasis. Quintana¹² described a case in which *Necator americanus* was present in the stools. Lavier, Bariety and Caroli¹³ have described a case of pulmonary infiltration with eosinophilia in a case of infestation with *Fasciola hepatica*. In the great majority of cases, no etiologic agent has been found.

The following case is reported because of the apparent rarity of the condition. A review of the

literature reveals but 4 such cases reported in the country.^{2, 11, 14, 16}

CASE REPORT

A 23-year-old soldier was admitted to the hospital on November 27, 1943. For several days prior to admission he had noticed unusual shortness of breath on moderate exertion. This was particularly evident when he ran up a embankment to his gun position. On November 26, he developed a sore throat, fever, generalized malaise and aching of the bones and muscles. On the morning of the 27th, he developed a shaking chill that lasted for 2 hours. On the day after admission, he developed a nonproductive cough associated with a dull, aching pain in the left side of the chest. He gave no history of hemoptysis, pleurisy or weight loss and no family history of tuberculosis. Careful questioning revealed nothing suggestive of allergy in the family or past history. There were no symptoms referable to the gastrointestinal or genitourinary system.

On admission, the temperature was 100°F., the pulse 84, and the respirations 20. The pharynx was granular and moderately injected. The lungs were resonant throughout. On auscultation numerous rhonchi were heard throughout both lung fields, being most marked at the bases posteriorly. No moist rales were noted. The area of cardiac dullness was not enlarged, the rhythm was regular, and no murmurs were heard. The aortic second sound was equal to the pulmonic. The blood pressure was 114/78. The abdomen was soft, and no organs or masses were felt.

The temperature dropped to normal in 24 hours, and the patient remained afebrile throughout the hospital stay. The pulse varied between 60 and 78, and the respirations were 20. On the 9th hospital day, the cough became productive of gradually increasing amounts of frothy, whitish, mucopurulent sputum, which eventually totaled 30 to 60 cc. a day. This persisted for 2 weeks and then gradually decreased, so that after 4 weeks the cough and expectoration of sputum ceased. On December 14, examination revealed diminished resonance at the right base, with numerous fine, moist rales at both lung bases posteriorly. The rales gradually decreased, and, on December 31 the lungs were clear on physical examination. The patient did not appear acutely ill at any time, and treatment for the most part was symptomatic. He received two doses of 3 cc. each of tetrachlorethylene and two courses of 1 gm. each of hexylresorcinol crystals, following which the ova of *Trichuris trichiura* (see below) disappeared from the stools. On January 20, he was started on 0.015 gm. of Mapharsen; this was followed by biweekly injections of 0.06 gm. of the drug for ten doses.

Repeated urinalyses were normal. Concentrated specimens revealed no evidence of ova or parasites in the sediment. Thirty-two stool examinations were negative for the ova of *N. americanus*, *Schistosoma mansoni* and *A. lumbricoides* and cysts and trophozoites of *E. histolytica*. On January 18 and 26, an occasional ovum of *T. trichiura* was found in the stool. Twenty-six sputum examinations revealed no evidence of tubercle bacilli, fungi, ova or parasites; a culture revealed *Staphylococcus aureus*. From December 9 to 18, examinations revealed a moderate to marked increase of eosinophils in the sputum.

Tuberculin tests were negative. An electrocardiogram was normal. Between January 13 and 15 the patient was skin-tested with twenty-four common allergens, with completely negative results. A sigmoidoscopic examination to a depth of 37 cm. revealed the bowel mucosa to be normal throughout, no hemorrhagic areas being seen. Agglutination tests and the brucellergen intradermal test for brucellosis were negative. An intradermal test with trichinella antigen was likewise negative.

Numerous thick blood films were negative for malarial and other parasites. Three midnight blood smears were negative for filariasis. Repeated examinations of blood smears revealed no abnormality of the erythrocytes. The eosinophils in the blood varied from 64 to 85 per cent during the first two months and had returned to normal (2 per cent) at the end of the third month (Table 1). The eosinophils were adult if judged by the nuclei, which were multilobed. On December 27, smears of the sternal marrow revealed it to be predominantly myeloid, and the elements present were of the

infiltration. These findings were not transitory. Repeated examinations over a period of six months revealed no significant changes. Diffuse pulmonary infiltration, fever and eosinophilia have been reported in chronic brucellosis,²¹ but in the present

FIGURE 3.

case the agglutination reaction and a skin test for brucellosis were negative. Trichinosis, which may have respiratory abnormalities as a significant feature of the disease,²² is rare in this locality, and could be excluded by the clinical course and negative skin test. Other tropical diseases characterized by blood eosinophilia were excluded by clinical and laboratory studies. Although trichuriasis may at times be associated with urticaria and a moderate eosinophilia, it is doubtful whether it was a significant etiologic factor. Recently, Weingarten²³ in India is characterized by a paroxysmal cough, expiratory dyspnea and occasional attacks of bronchial asthma, with mucopurulent sputum often containing clumps of eosinophils. A low-grade fever, a moderately enlarged spleen, an eosinophilia up to 88 per cent and a moderately accelerated sedimentation rate

was present. The case reported appears to be typical of the Loeffler syndrome in that the condition was benign, there was practically no elevation of temperature, the pulmonary infiltration shifted during the course of the disease, and a marked peripheral eosinophilia was present. A case of Loeffler's syndrome is presented. The eosinophilia was more marked than it has been in the majority of reported cases, and appeared to respond to treatment with Mapharsen. No definite etiologic agent was found.

infiltration. These findings were not transitory. Repeated examinations over a period of six months revealed no significant changes. Diffuse pulmonary infiltration, fever and eosinophilia have been reported in chronic brucellosis,²¹ but in the present

FIGURE 3.

case the agglutination reaction and a skin test for brucellosis were negative. Trichinosis, which may have respiratory abnormalities as a significant feature of the disease,²² is rare in this locality, and could be excluded by the clinical course and negative skin test.

Other tropical diseases characterized by blood eosinophilia were excluded by clinical and laboratory studies. Although trichuriasis may at times be associated with urticaria and a moderate eosinophilia, it is doubtful whether it was a significant etiologic factor. Recently, Weingarten²³ in India described what he believes to be a new clinical entity, manifested by severe, paroxysmal bronchitis and a high eosinophilia, in which arsenicals are a specific and quickly acting remedy. The disease is characterized by a paroxysmal cough, expiratory dyspnea and occasional attacks of bronchial asthma, with mucopurulent sputum often containing clumps of eosinophils. A low-grade fever, a moderately enlarged spleen, an eosinophilia up to 88 per cent and a moderately accelerated sedimentation rate

are usually present. X-ray examination reveals disseminated 'mottling' of both lungs, indicating small bronchopneumonic infiltrations. Although benign, this disease may last for several years. Arsenicals are specific, and the eosinophilia disappears rapidly after several injections. This was the basis for the treatment of our patient with Mapharsen.

The case reported appears to be typical of Loeffler syndrome in that the condition was benign; there was practically no elevation of temperature; the pulmonary infiltration shifted during the course of the disease, and a marked peripheral eosinophilia was present.

SUMMARY

A case of Loeffler's syndrome is presented. The eosinophilia was more marked than it has been in the majority of reported cases, and appeared to respond to treatment with Mapharsen. No definite etiologic agent was found.

MEDICAL PROGRESS

THE PORPHYRINS*

MERRILL L. WELCKER, M.D.†

BOSTON

THE average physician confronted with the subject of porphyrin metabolism pictures either a bewilderingly complex group of strange pigments obtained from stools and urine or an exceedingly rare disease characterized by sensitivity to light and acute abdominal pain. Actually, porphyrin derivatives are an essential part of the respiratory enzymes present in all living cells, and an understanding of their nature and relations may be expected to lead to improvement in the diagnosis and treatment of many human diseases. It is the purpose of this paper to discuss one of these porphyrins, protoporphyrin, and to indicate the role it plays in normal and abnormal human metabolism.

PROTOPORPHYRIN

The important chemical and physiologic roles of the substance protoporphyrin concern its integration into the iron-containing enzymes and pigments. Heme or hematinlike substances are formed when iron enters the center of the protoporphyrin ring, and the heme group combines with various specific proteins to form compounds such as blood hemoglobin, muscle hemoglobin, catalase, peroxidase and the cytochromes. These are essential and widely distributed substances in the body, and their specific physiologic or enzymatic functions are determined by the type of protein attached to the heme group. Although the heme group does not determine the specific function, it is nonetheless important as a common denominator of this whole group of substances. As compared with its appearance in these iron compounds, protoporphyrin free of iron and protein does not occur in large amounts in the body. It is present largely in the young cells of the red-cell series in the bone marrow and the peripheral blood.

Protoporphyrin was first found to be an iron-free derivative of hemoglobin by Kämmerer¹ in 1923. He demonstrated this by diluting blood with broth and inoculating it with fecal bacteria and putrid material from gangrenous lesions and bronchiectatic cavities, and incubating it for four to six days. Hoagland² had shown in 1917 that sterile autolysis of muscle resulted in a pigment identical with protoporphyrin, which by further hydrolysis changed

into hematoporphyrin. In 1924, the porphyrin present in natural hemin was crystallized and was shown by Fischer³ to be protoporphyrin. Other studies followed.⁴⁻⁷

Protoporphyrin occurs in feces as a bacterial decomposition product of hemoglobin, and is chiefly exogenous.⁸⁻¹⁰ Formation also takes place by bacterial decomposition of different types of tissue, such as the calf's heart and the liver, lung and uterus of various species.⁵ Protoporphyrin 9 has been found in sheep liver by Rimington.¹¹ Excluding the above sites, the distribution of protoporphyrin in nature is somewhat bizarre. It is found in large amounts in the Harderian gland of the rat family.¹² It is apparently an excretion product of this gland, and none is produced for utilization in the animal. Protoporphyrin occurs as a pigment of the egg shells of certain birds, such as the plover, that nest in the open.¹³ It has been found in incubated hens' eggs.¹⁴ It is present in alkalized yeast, in plants such as peas, corn and beans and in the leaves of the ash and the maple.¹⁵⁻¹⁹

RELATION OF PROTOPORPHYRIN TO OTHER PORPHYRINS

Considerable knowledge of the structure and chemical properties of the various porphyrins exists, but the physiologic relations are rather obscure. All the porphyrin compounds consist of a basic porphyrin ring made up of four pyrrol groups attached to each other by methene linkages. The identity of a particular porphyrin is the result of the type and position of radicals attached to eight substitution points along the porphyrin ring. Porphyrin compounds in the body fall into two groups — first, those having four each of two different radicals in the eight substitution points along the porphyrin ring, and second, those having three radicals divided into four of one type and two each of the others. The first group has four possible isomers and the second has fifteen.

Examples of the first group are coproporphyrin and uroporphyrin. Both have four of two different types of radicals attached to the porphyrin ring. The four isomers that any porphyrin in this group may conform to are termed "types" and are numbered from 1 to 4. Only Types 1 and 3 are found

in nature. Types 2 and 4 do not occur naturally but have been synthesized. Types 1 and 3 are shown in Figure 1.

Porphyrins of the second group are characterized by three different radicals substituted and fifteen isomers; in this group are included deuteroporphyrin, mesoporphyrin, hematoporphyrin and protoporphyrin. Each of the fifteen isomers conforms to one of the four types in the first group of simpler porphyrins. Examples of these compounds are shown in Figure 2.

The uroporphyrins and coproporphyrins are more carboxylated than protoporphyrin or the other more complex porphyrins. If the two vinyl groups of protoporphyrin are saturated and a carboxyl group is added, it is transformed into coproporphyrin. If, further, coproporphyrin has the four methyl groups altered and carboxylated to acetic groups, a transformation arises whether such a carboxylation occurs in the body and whether the simpler porphyrins are excretion products of protoporphyrin.

Before an attempt is made to answer this question, certain important concepts concerning the relations of "enzymatic control," partial credit for which should be given to Dobriner,²² Rimington²³ has hypothesized that a ratio exists between the Type 3

compound, it follows that if this substance has porphyrin precursors or derivatives, these must also be Type 3 porphyrins. According to this hypothesis uroporphyrin 1 and coproporphyrin 1 could never be incriminated as precursors or derivatives of Type 3 protoporphyrin.

A second concept consists of Rimington's²⁴ theory of "enzymatic control," partial credit for which should be given to Dobriner.²² Rimington has hypothesized that a ratio exists between the Type 3

A second concept consists of Rimington's²¹ theory of "enzymatic control," partial credit for which should be given to Dobriner.²² Rimington has hypothesized that a ratio exists between the Type 3

and the Type 1 series of porphyrin compounds in the body, this ratio being greatly in favor of the former. The explanation lies in the hypothetical formation of porphyrins from two dissimilar dipyrromethenes — each one half a porphyrin ring with suitable radicals attached, — which may be designated as X and Y. The radicals of the dipyrromethenes are arranged so that when X and Y unite a porphyrin such as protoporphyrin 9 (Type 3) is formed. This reaction is controlled by enzymes, but a small fraction of X molecules combine with other X molecules to form a Type 1 porphyrin. It would be reasonable to expect that a small fraction of dipyrromethene Y molecules would combine with each other to form a Type 2 porphyrin, but

uroporphyrin and their isomers occur in the body if mesoporphyrin^{23,24} and deuteroporphyrin²⁵⁻²⁷ are excluded as exogenous in the feces. Vigorous investigation of uroporphyrin and coproporphyrin has revealed few generalizations. Uroporphyrin and coproporphyrin are found largely in the urine and feces.²³ Coproporphyrin is considered the only porphyrin normally present in urine.^{29,30} Some authorities³¹ report that normal bile contains coproporphyrin I, and other investigators³² find no coproporphyrin in bile. When an increase of uroporphyrin or coproporphyrin occurs in disease, the normal liver causes Type 1 porphyrins to be excreted in both the urine and the bile, but Type 3 isomers of these substances are excreted exclusively in the urine.²⁵ Copropor-

FIGURE 3.

none of this has ever been found in nature or the body. This discrepancy has been anticipated by postulating that the only leak in the reaction centers around the combination of similar X molecules, the enzyme system entirely preventing the combining of Y molecules. The whole reaction is theoretically tenable and can be expressed structurally as shown in Figure 3. These theories furnish a convenient explanation for the presence of uroporphyrin and coproporphyrin I in the body as breakdown products either of Type 1 protoporphyrin or of some other as yet undiscovered complex Type 1 porphyrin. Another theory presupposes that uroporphyrin 3 and coproporphyrin 3 are formed directly from dipyrromethenes and that the Type 1 analogues occur as an artefact of their synthesis.

The occurrence of porphyrins in the diseased and normal body should be briefly summarized in a search for facts correlating with these theories. Besides protoporphyrin only coproporphyrin and

pyrin excretion in the urine and the urinary fecal ratio have been thought to be sensitive tests of hepatic function,²⁵ but this is not so.³³

In diseases characterized by marked increases of uroporphyrin and coproporphyrin there has never been found any abnormality of the protoporphyrin metabolism. Such diseases are known as porphyria if they are due to inborn errors of metabolism or as porphyrinuria if secondary to other diseases. Congenital porphyria has the clinical features of photosensitivity, red teeth and bones and dark-red or brown urine.³⁴ Uroporphyrin 1 and 3 are deposited in the skeleton, and Type 1 isomers of uroporphyrin and coproporphyrin are found in large amounts in the urine. Acute porphyria is associated with acute episodes of abdominal cramps, neurogenic paralyses and mental symptoms, and also with dark urine.³⁵ The urine contains large amounts of Type 3 uroporphyrin and coproporphyrin. No involvement of protoporphyrin has been found to occur in these

diseases, and there are present no marked anemias that might be attributed to an error in the formation of protoporphyrin. Applying the theory of enzymatic control to congenital porphyria, the increases of Type 1 porphyrins could be interpreted as a lack of the normal retardation of these compounds, resulting in an abnormal ratio between the Type 1 and Type 3 porphyrins. No protoporphyrin I has ever been reported in patients with this disease.

The porphyrinurias are diseases in which the excess of porphyrin is usually coproporphyrin of either type secondary to other disease, such as liver disease,³⁶ pellagra,³⁷ febrile conditions³⁸ and diseases of the blood-forming organs. Protoporphyrin has never been involved, except in diseases in which anemia exists, which will be treated under a separate heading.

It has been assumed by most authors that Type 3 coproporphyrin and uroporphyrin may well be excretion products of a more complex, specialized porphyrin compound such as protoporphyrin. Schumm³⁹ in 1923 found no coproporphyrin in the urine of patients on a meat-free diet and was able to demonstrate its appearance following feeding with hemoglobin and blood sausage. In 1926, he⁴⁰ found increased coproporphyrin in the feces following similar feedings. Van den Bergh et al.⁴¹ attempted to prove that the liver changes protoporphyrin to coproporphyrin by perfusing livers with protoporphyrin solutions and demonstrating coproporphyrin in the bile in increased amounts. The isomer of protoporphyrin was not identified. Vigliani and Sonzini⁴² in a similar experiment found no coproporphyrin and most of the protoporphyrin that was administered present in the bile in a patient with a complete external biliary fistula. By far the most conclusive investigations on this subject were those of Watson, Pass and Schwartz,⁴³ who repeated and modified van den Bergh's experiments. Only increases of Type 1 coproporphyrin were demonstrable, and these increases, although distinct, were small and represented only a fraction of the administered protoporphyrin. It is impossible for coproporphyrin 1 to be a direct product of protoporphyrin 9, so that to explain the increase of the latter it must be hypothesized that protoporphyrin stimulates synthesis of coproporphyrin 1 in some unknown fashion.

The hypothesis of so-called "dualism of the porphyrins" would be immeasurably strengthened if it could be demonstrated that small amounts of a Type 1 protoporphyrin are present in hemoglobin along with the usual Type 3 protoporphyrin. This would establish a highly specialized functioning end product of the Type 1 series of porphyrins and afford a substance from which coproporphyrin and uroporphyrin 1 could be reasonably derived. When Fischer⁴⁴ in 1939 described experiments identifying a small fraction of natural hemoglobin as containing protoporphyrin 2, a Type 2 compound, wide inter-

est was aroused and the matter was considered as solved. His experiments depended on the transformation of protoporphyrin to mesoporphyrin, with esterification and identification of the latter. However, in a second, obscurely titled paper, Fischer and Schroder⁴⁴ retracted the earlier findings on the identification of mesoporphyrin 2 (Type 1) as a derivative of the hemoglobin of normal blood. Conversions of the supposed mesoporphyrin 2 to rhodins and verdins showed no trace of mesorhodin 2 or mesoverdin 2. The conclusions of these workers were that no protohemin 2 (Type 1) exists in normal blood.

These facts change considerably the attitude toward the Type 1 porphyrins, uroporphyrin and coproporphyrin. There are no other Type 1 porphyrin compounds known in the body from which they might be derived or into which they might change. There is no evidence at present that they are anything more than abortive side products of porphyrin synthesis. Relegating them to an abortive state does not by any means invalidate the theory of dualism of the porphyrins or that of enzymatic control. The term "abortive" in this sense refers to structural evolution and function, and not to quantity or pathologic significance.

Certain miscellaneous aspects of the relations of protoporphyrin to the other porphyrins must be mentioned. Properties of photosensitization common to several of the porphyrins have not been found to be shared with protoporphyrin.⁴⁵ It is never deposited in the bones, as is uroporphyrin.⁴⁶ Porphyrins of several types have been known to combine with proteins such as fibrinogen, albumin and globin.^{46,47} Light hydrolyzes the proteins in the presence of porphyrin and oxygen. Fischer⁴⁸ has suggested a correlation of the toxicity of the porphyrins with the number of carboxyl groups present in each. The order of toxicity as judged by the production of light shock in mice is as follows: hematoporphyrin 9, Type 1 uroporphyrin, deutero-porphyrin 9, Type 1 coproporphyrin and protoporphyrin 9; Type 3 coproporphyrin is only slightly toxic, and uroporphyrin 3 is nontoxic.⁴⁸

PRECURSORS OF PROTOPORPHYRIN

The steps in the formation of protoporphyrin *in vivo* are unknown. In 1929, Fischer^{49,50} synthesized heme from simple pyrrols. Dipyrromethenes were formed from pyrrols and then condensed to a Type 3 porphyrin that in a series of steps became protoporphyrin 9. In the body Fischer²⁰ has suggested simpler sources, such as proline, oxyproline and tryptophane. Dipyrromethenes probably form a step in the synthesis. There are two clues to the presence of dipyrromethenes in the body—the pentdyopent reaction and the porphobilinogen test. In neither of these reactions has a dipyrromethene been shown to exist free inside the body. The pentdyopent reaction consists of a spectroscopic

absorption band appearing at 525 millimicrons when hemoglobin, heme, bilirubin or urobilin solutions are treated with hydrogen peroxide, particularly in alkaline solution in the presence of sodium hydrosulfite.²⁰ Fischer and Stern³¹ have identified the substance producing the absorption band as a dipyrromethene. The relation of protoporphyrin to the pentdyopent reaction is mentioned only twice in the literature. Hulst and Grotepass⁵² state that pentdyopent may be prepared from protoporphyrin, although the oxidative process is much slower. Fischer and Müller⁵³ report that none of the porphyrin compounds, including protoporphyrin, give the pentdyopent reaction. The porphyrin ring can be readily broken down to the dipyrromethenes found in the pentdyopent reaction if iron and globin are attached or if it has already been broken down to a straight chain of four pyrrol groups, as in bilirubin or urobilin:

Porphobilinogen was first noted in the urine as the substance in porphyria that gave a positive Ehrlich reaction not due to urobilinogen. It was discovered by Waldenström⁵⁴ in 1937. It is considered to be a dipyrromethene, and a simple test for it has been devised and the literature reviewed by Watson.⁵⁵

BREAKDOWN OF THE PROTOPORPHYRIN RING

This subject is intimately tied up with the breakdown of hemoglobin and the iron enzymes. The probability of breakdown through uroporphyrin and coproporphyrin has already been discussed. The vast majority of protoporphyrin in hemoglobin is broken down and eliminated as bile pigments, and degradation to porphyrins is minimal. Iron does not separate from the heme until the porphyrin ring has been split open,^{56,57} thus avoiding a free porphyrin stage.

In 1935, Schreus and Carrié⁵⁸ reported the formation of protoporphyrin by the action of ground-up liver on hemoglobin at 36 to 60° C. They believed that the effect was due to an enzyme that they called "hemase," and considered the formation of protoporphyrin intermediate in the breakdown of hemoglobin to bile. When the reaction was alkaline, bile formed, but this occurred at a higher maximum temperature, attributed by them to the possible destruction of catalase. These findings have never been confirmed, but if true are of great importance. Evidence militates against such a process predominating *in vivo* because of Lemberg's⁵⁶ demonstration that in hemoglobin the porphyrin ring is split open prior to the departure of the iron.

RED CELLS AND HEMOGLOBIN

Protoporphyrin was first found in red cells by van den Bergh and Hyman⁵⁹ in 1928. Grotepass⁶⁰ isolated it and identified it as a Type 3 porphyrin. The association of protoporphyrin and reticulocytes was noted by two different groups. Watson and

Clarke⁶¹ ingeniously showed that most of the protoporphyrin is contained in the reticulocyte-rich stratum of centrifuged cells. They were also able to show that protoporphyrin is mutually precipitable with certain stains, such as cresyl blue, that stain reticulocytes. The precipitated protoporphyrin-dye substance microscopically resembles the framework of reticulin in reticulocytes, but the precipitation phenomenon is probably due to a buffering effect and not to the formation of an actual compound between the protoporphyrin and the dye.⁶² De Langen and Grotepass⁶³ arrived at similar conclusions concerning the large amount of protoporphyrin in reticulocytes. Seggel^{64,65} presents evidence that the erythrocyte protoporphyrin resides in cells called "fluorescytes," which can be identified only by their fluorescence in ultraviolet light. These cells normally occur in largest numbers in the bone marrow, their appearance and increase in the peripheral blood being associated with conditions causing reticulocytosis. Seggel has pointed out that fluorescytes appear later and decline more slowly than do reticulocytes in cases of pernicious anemia under liver treatment. Watson's⁶² latest studies reveal a discrepancy between erythrocyte protoporphyrin levels and reticulocyte percentages in treated cases of pernicious anemia. This casts some doubt on whether all reticulocytes contain large amounts of protoporphyrin. To explain this discrepancy Watson has mentioned the possibility that in the peak of the reticulocyte response following liver therapy in pernicious anemia there may be a large number of reticulocytes that have had a megaloblastic origin and do not contain much protoporphyrin. Incubation of red cells for twenty-four to forty-eight hours resulted in a decrease of the reticulocytes but an increase of protoporphyrin. When experimental phenylhydrazine anemia was produced in rabbits, the protoporphyrin in red cells more nearly paralleled the reticulocytes than in pernicious anemia. Reticulocytes derived from megaloblasts would presumably not be present in the phenylhydrazine anemia.

The status of protoporphyrin in the bone marrow is not entirely clear. Borst and Königsdorffer⁶⁶ found it in normal marrow and increased in certain conditions, notably pernicious anemia. It was contained largely in erythroblasts and megaloblasts and occurred in the megaloblasts in pernicious anemia. It is generally conceded that the bone marrow contains large amounts of protoporphyrin in pernicious anemia,^{32,55} but there is a difference of opinion about its presence in megaloblasts. Seggel and his co-workers were unable to find it there before or after treatment. Stasney and McCord⁶⁷ found protoporphyrin in megaloblastic marrow, but the amount increased as the marrow became normoblastic.

Lead poisoning has been found by Vigliani and his co-workers^{68,69} to give rise to high protoporphyrin

levels in the red cells and plasma. This disease has long been associated with increased amounts of coproporphyrin 3 in the urine. In most diseases showing hyperactive erythropoiesis it is coproporphyrin 1 that is found in abnormal amounts. This finding is so regular that the presence of coproporphyrin 1 in the urine is said to be an index of increased erythropoiesis. In pernicious anemia coproporphyrin 1 has been found increased in the urine and plasma in relapse.^{31,32} Rimington⁷⁰ has shown that coproporphyrin 3 predominates in the urine following sulfanilamide treatment. Both Rimington and Watson⁷¹ have hypothesized that lead and sulfanilamide may interfere with the introduction of iron into the porphyrin molecule, resulting in the formation and excretion of coproporphyrin 3. Very few other investigations of protoporphyrin in diseases of the blood have been made except for Watson's⁶² preliminary studies employing the photoelectric method, which showed moderately elevated levels in several diseases associated with reticulocytosis.

Peripheral red-cell protoporphyrin should probably be considered as a supply of one of the building blocks of hemoglobin. Increased supplies in the peripheral blood occur in conditions characterized by rapid formation of red cells in the marrow and the premature throwing off of some forms of young red cells into the circulation. The factors governing the release of these cells from the bone marrow apparently regulate the peripheral blood-protoporphyrin level. Such factors include the pathogenesis of the particular anemia, depletion of the peripheral red cells and the ability of the bone marrow to regenerate young forms. Increased protoporphyrin levels are probably secondary to these conditions. The temptation must be resisted to consider that in pernicious anemia there is an arrest of protoporphyrin synthesis, with resumption of this synthesis manifested by the increased protoporphyrin following the administration of liver extract.

PROTOPORPHYRIN IN URINE

In kidneys perfused with various porphyrins, Grotepass and Hulst⁷² reported that uroporphyrin was excreted rapidly by the kidney, coproporphyrin less so, and protoporphyrin not at all. In spite of the vast quantity of research done on urinary porphyrins, there has been only one report of protoporphyrin in the urine. Boas⁷³ in 1933 reported finding protoporphyrin in the urine of diabetic patients with jaundice, cholelithiasis, carcinoma of the gall bladder and other conditions. He used the ordinary ether-acetic and hydrochloric acid extraction methods. All other observers are in complete agreement that protoporphyrin has never been found in urine. No protoporphyrin has ever been reported in the hemoglobinurias or myoglobinurias or following the breakdown of red cells in the urine, as in hematuria.

PROTOPORPHYRIN IN ENZYMES

Fischer and Orth²⁰ have reviewed the early work on the identification of Type 3 porphyrins in enzymes and pigments. The more recent studies have been covered by Sumner and Somers.⁷⁴ The porphyrin in myoglobin was identified by Schönheimer⁷⁵ in 1929 as protoporphyrin. In spirographis hemin the porphyrin present is Type 3 protoporphyrin.¹²

Although not an oxidase, catalase is classified with the oxidases because of its structural similarity to them and because of its close connection to physiologic oxidation. It occurs in all forms of life except a few micro-organisms, and its action consists of protecting living things from hydrogen peroxide. Zeile and Hellström⁷⁶ showed that catalase is a hematin compound. Later, Stern⁷⁷ demonstrated that the hematin of catalase is protohematin 9. The highest concentrations are in the erythrocytes and liver.

Another important enzyme, peroxidase, occurs in all plant cells, although its occurrence in animals is problematical. It catalyzes the oxidation of large numbers of phenols and amines in the presence of hydrogen peroxide. Theorell⁷⁸ demonstrated it to be a hematin-protein compound. Verdoperoxidase, so called because of its color in the dry state, has a similar action and occurs to the extent of 1 per cent in white blood cells.⁷⁴ It contains 0.1 per cent iron and is assumed to be a heme-protein compound.

Cytochrome is widely distributed in nature and in the body. The bulk of investigation has been on cytochrome C because Types A and B are extremely labile. Cytochromes probably function as carriers of electrons and thus participate in complicated reactions leading to the removal of hydrogen from metabolites and the formation of water. Cytochrome C is a hematin-protein compound whose heme group differs from protoheme in having a tertiary-ring base condensed around it. It is bound to protein by two histidine-imidazole groups attached to iron on either side of the flat hematin disk and by thioether bindings to the ethyl groups (the ethyl groups taking the place of the usual vinyl radicals).^{79,80} These bindings to the protein explain why cytochrome is not auto-oxidizable, since oxygen cannot approach the iron; for the same reason, cytochrome cannot unite with carbon monoxide or cyanide at ordinary pH values.

The isomer of protoporphyrin has not been identified in the case of all the iron enzymes. No such exhaustive study has been made on any of the enzymes as that by which Fischer excluded the presence of protoporphyrin 2 (Type 1) in blood. In the review of these compounds it can be seen that protoporphyrin and iron appear to be inseparable in any physiologic role, and that they are combined with a protein. A generalization can probably be made that neither protoporphyrin alone nor iron occurring alone, as in hemosiderin,⁸¹ have any useful function or physiologic role.

MISCELLANEOUS STUDIES CONCERNING PROTOPORPHYRIN

According to Hinsberg and Rodewald,⁸² administration of protoporphyrin and hematoporphyrin to various animals resulted in an increased melanophore-distributing hormone of the hypophysis. The injected animals formed a substance inactivating this hormone, and the authors associate this inactivating agent with the serum of cancer cases. Hinsberg⁸³ also reported premature follicle formation in the ovaries of mice following injection of protoporphyrin and hematoporphyrin.

CHEMICAL ASPECTS OF PROTOPORPHYRIN

Fischer and Orth²⁰ have described the physical and chemical properties of protoporphyrin. It has been crystallized in two forms, and the crystals are usually yellow to reddish. It is soluble in chloroform, pyridine and ether, in acetic and hydrochloric acids and in aqueous solutions of alkalis. It is reddish in solution, like the other porphyrins. All the porphyrins produce intense absorption bands in the visible spectrum. The number and position of the bands vary with the pH, the temperature and the solvent, but under standard conditions the bands are characteristic for a given compound, all isomers having the same bands. A listing of the differentiating absorption bands of the porphyrins cannot be found in the English literature. Table 1 is modified from Vannotti.⁸⁶

Protoporphyrin is differentiated from the other porphyrins by its spectroscopic bands, by the melt-

The fifteen isomers of protoporphyrin have not yet been separately synthesized, but Fischer and Orth²⁰ have synthesized twelve of the fifteen isomers of mesoporphyrin. Protoporphyrin and its methyl ester are unstable, particularly in the presence of light, and for isomeric or quantitative determinations it is customary to convert the protoporphyrin to mesoporphyrin and form the methyl ester of the latter. The esters of all the porphyrins crystallize more easily than do the porphyrins themselves, and the ester melting point is more distinct. Watson⁸⁴ has recently summarized the methods of conversion of protoporphyrin to its methyl ester, and has added an improved micromethod involving the reduction of hydriodic acid, acetic acid and ascorbic acid.

Protoporphyrin can be prepared in many different ways,^{1,2,85} but the most convenient method is that of Fischer and Pützer,⁸⁶ whose description of it has never been translated into English. This method is as follows:

Six grams of hemin are heated to boiling with 300 gm. of formic acid of specific gravity 1.22. Six portions of 1 gm. each of finely powdered iron (specifically, "Kahlbaum for analysis") are introduced at five-minute intervals into the boiling liquid and boiled for fifteen more minutes after the last has been added. To avoid bumping it is necessary to shake the apparatus in a machine. After the total time reaction of forty minutes the entire hemin is transformed into porphyrin. It is then cooled off and filtered from the iron and the formed ferroformate. Protoporphyrin is precipitated by diluting with two to three volumes of water and adding solid ammonium acetate. The precipitate is freely washed with water and dried. In the filtrate there remains a small amount of protoporphyrin and much iron.

Grinstein and Watson⁸⁷ have recently reviewed the methods of purification of the crude product and have

ing points of its methyl esters, by its solubility in sodium hydroxide and by its hydrochloric acid number. The hydrochloric acid number is the concentration in percentage of hydrochloric acid that, when shaken with equal parts of ether, removes two thirds of the porphyrin from the ether. Dobriner⁸⁸ gives a table of these constants that is taken from Fischer and Orth.²⁰

modified Hamsid's method. The protoporphyrin is dissolved in a small amount of chloroform, and petroleum ether is added until a precipitate begins to form; crystallization is completed in an icebox. Further purification occurs on forming the dimethyl ester, and Watson⁸⁷ has devised a method of purification of the ester using chromatography and eluting a chloroform-dissolved ester with

petroleum ether.⁸⁷ A method of transformation of protoporphyrin to protohemin is described by Fischer and Pützer⁸⁶ in which ferrous acetate or ferric chloride is allowed to combine with protoporphyrin, depending on whether divalent or trivalent iron is to be added.

Grinstein and Watson⁸⁸ review the older methods of extraction of free protoporphyrin from blood cells and present a new modification. Previous methods used spectroscopic or fluorometric determinations of the protoporphyrin. Watson's method employs the photoelectric colorimeter's measurement of the absorption of light at 400 millimicrons, the maximum absorption band of protoporphyrin being at 407 millimicrons. It has the advantages over any one of the older methods of simplicity and accuracy. It has much wider possibilities for clinical investigative studies than do the other methods. In brief, the primary extraction is made with a mixture of glacial acetic acid and ethyl acetate, followed by successive extractions with hydrochloric acid, ether and again hydrochloric acid. Values are expressed in gamma per 100 cc. of erythrocytes, normal values ranging from 20 to 45. In disease, protoporphyrin may be elevated to 200 and even 430 gamma.⁶²

Extraction of other organs and tissues usually depends on acetic acid-ether extracts of the ground tissues, purification being done by a series of extractions involving hydrochloric acid and ether. Neutralization of the hydrochloric acid solution with acetate, using Congo red as an indicator, drives the porphyrin back into the ether. Hydrochloric acid solutions of over 5 per cent always extract the porphyrin from the ether. The protoporphyrin in liver has been extracted in this manner by Fischer⁸⁹ and by Rimington.¹¹

SUMMARY

It may be said that protoporphyrin is intimately associated with certain of the pigments and enzymes concerned in oxidative processes. Iron and protoporphyrin have always been found in combination in physiologic conditions. Neither has been proved to have any important separate functional capacity. The protoporphyrin forms a convenient and suitable binding necessary to the iron.

Circumstantial evidence points to coproporphyrin 3 and uroporphyrin 3 as excretory products of protoporphyrin. Coproporphyrin 1 and uroporphyrin 1 cannot be breakdown products of protoporphyrin 9, the only protoporphyrin known in the body. If in the future a Type 1 porphyrin is found in a pigment or enzyme, uroporphyrin 1 and coproporphyrin 1 will be acceptable as its possible excretion products. In the meantime they must be considered as abortive side products of porphyrin synthesis.

Protoporphyrin is found free in red cells, and is associated with certain young cells called "fluorescytes" and with reticulocytes. In diseases in

which these cells are numerous, the red-cell protoporphyrin increases and can be considered a supply for the building up of hemoglobin. Many recent advances have been made relating to qualitative and quantitative determinations. Clinical investigation of the protoporphyrin of blood in disease has been facilitated.

CASE 31011

PRESENTATION OF CASE

First admission. A fifty-five-year-old woman was admitted to the hospital with an impacted fracture of the neck of the right femur.

About twenty-four hours before admission the patient became dizzy and fell to the floor. An x-ray examination revealed an incomplete impacted fracture of the right femoral neck. Four years previously the patient had fallen at home and incurred a similar fracture of the left femoral neck, which was treated by traction with a good result. One and a half years prior to admission she had fallen on her left shoulder with a resultant impacted fracture of the surgical neck of the left humerus which also healed with a good result. At about that time she had had an attack of "nervous prostration" lasting six weeks, with frequent "dizzy" or "sinking" spells, which caused her to fall down. About two months before entry she had fallen and twisted her ankle. The patient was said to have had congenital syphilis; this was diagnosed at the age of three years and apparently was inadequately treated. Her teeth had been poor and were extracted at an early age. She had two adult children by her first husband; both were born after a full-term normal pregnancy and both had negative Hinton tests. She had been married to her second husband for two and a half years.

Physical examination on admission revealed a fairly well-developed and well-nourished woman incessantly picking at the bedclothes or rubbing her hands together; she was vague about her past history and unco-operative. There was spasm about the right hip and limitation of motion but no shortening.

The temperature was 99°F., the pulse 86, and the respirations 20. The blood pressure was 130 systolic, 70 diastolic.

Examination of the blood showed a red-cell count of 4,010,000, with 75 per cent hemoglobin, and a white-cell count of 6800. The urine varied in specific gravity from 1.002 to 1.014, with a 0 to a ++ test for albumin and a sediment containing few to many white cells and a few red cells. The blood protein, calcium, phosphorus and phosphatase levels were

normal. Blood Hinton and Wassermann tests were positive.

Since the fracture was impacted and in good position, it was treated with balance suspension. The patient throughout her stay was unco-operative, suspicious and difficult to manage. A psychiatric examination showed her to be emotionally unstable — "irritable and belligerent, but not demented or psychotic"; there was no confusion or impairment of memory. At the end of six weeks the patient resisted efforts to get her up on crutches, and she was discharged against advice.

Second admission (four months later). Following her discharge the patient was able to get about a little, but her activity was limited by the frequent occurrence of "sinking" spells, during which she became weak and was forced to sit down for a time. Six hours before entry, her husband left her feeling quite well. Half an hour before entry he returned and found her in her chair, comatose and stiff.

Physical examination revealed a comatose woman breathing in gasps. The only response was slight withdrawal of the extremities from painful stimuli. All the extremities were spastic. The head and eyes were turned to the left. There were spontaneous, horizontal, nystagmoid movements. The pupils did not react to light. There was no papilledema. All the deep tendon reflexes were brisk, particularly on the left. There were bilateral extensor plantar responses, and a positive Hoffmann sign on the left.

A lumbar puncture revealed clear fluid under a pressure equivalent to 130 mm. of water and containing 6 lymphocytes and 15 red cells per cubic millimeter. The total protein was 234 mg. per 100 cc. The Wassermann test was positive. The gold-sol curve was 5555555500. The urine had a specific gravity of 1.022, with no albumin or sugar but with a ++ test for acetone and a rare granular cast in the sediment.

The temperature on admission was normal, but four hours later it spiked to 105°F. and during the next twenty-four hours it rose to 108°F. The pulse rose to 160 and the respirations to 50.

The white-cell count was 16,100, with 80 per cent neutrophils. A blood culture was negative. A roentgenogram of the chest taken at the onset revealed indefinite fine areas of increased density in the left lung field. X-ray examination of the skull was negative. Sulfadiazine was administered (1.0 gm. every six hours) by Levine tube, and food and fluid intake were maintained in the same fashion. A second lumbar puncture revealed a cell count of 29 lymphocytes, 7 neutrophils and 29 red cells.

After reaching 108°F. on the third hospital day, the temperature gradually fell toward normal. The patient remained comatose. Deviation of the head and eyes to the left occurred intermittently. At times there was skew deviation of the eyes. On one occasion the pupils were reported to react slightly to light. The extremities were sometimes spastic and

*On leave of absence.

sometimes flaccid. At times the tendon reflexes could not be obtained.

On the fourth hospital day, the temperature rose to 101°F., the lungs filled with coarse moist rales and the patient died.

DIFFERENTIAL DIAGNOSIS

DR. RAYMOND ADAMS*: Let us scrutinize this record with the purpose in mind of selecting data that point to the site of the pathologic process, leaving the matter of etiology until later.

In the early part of the history the outstanding symptoms were attacks of dizziness and sinking spells. In such attacks the patient had fallen repeatedly and had suffered numerous injuries. The first problem that confronts us, then, is the nature of these spells. Were they attacks of giddiness such as occur so often in nervous, anxious individuals, or were they attacks of vertigo such as are often observed in diseases of the labyrinth, eighth nerve or vestibular nuclei? Were they straightforward syncope attacks, brief seizures or apoplectic phenomena? I shall assume, for the reason that the patient repeatedly fell and injured herself, apparently having at the moment none of the usual protective reflexes against injury, that they were not giddy or vertiginous spells but either epileptiform or apoplectiform attacks. The description is inadequate to make a sharp distinction between these two.

The examination at the first hospital entry disclosed some interesting findings. The patient was picking at the bedclothes, rubbing her hands together, unable to relate the history of her illness, unco-operative and apparently lacking in insight. Further notes point out that she was suspicious and difficult to manage, being emotionally unstable and belligerent. Even though the psychiatric consultant reassures us that the patient was not "demented or psychotic," I do not recognize this as normal. Change in personality, lack of insight, confusion, emotional instability, irritability and suspiciousness are marks of intellectual deterioration due to a disorder of the brain. If acute, it may be on a toxic basis, but if chronic, as it was in this case, it is indicative of structural brain disease often termed an organic reaction type by psychiatrists. These signs, of course, have no specific localizing value but point to a diffuse involvement of the cerebrum.

The symptoms that precipitated the second admission were much more dramatic. Six hours before entry the patient had appeared quite well, and a few hours later she was found in coma. In addition, the extremities were stiff and rigid, the head and eyes deviated to the left, the eyes jerked from side to side, the pupils were unreactive, and the plantar responses were bilaterally extensor. It seems to me that the patient at that time was functioning at

essentially a brain-stem level. The description of the position of the limbs is incomplete, but it is possible that she was assuming postures seen in decerebrate rigidity. The most we can conclude is that there was abrogation of all cerebral function.

There are two possible explanations of the spontaneous nystagmoid movements. There might have been a lesion in the vestibular nuclei or in the connections between these nuclei and the third, fourth and sixth nuclei by way of the medial longitudinal fasciculus. If these nystagmoid movements were always toward one side they might have been caused by a focus of irritation, that is, epilepsy, in the contralateral cerebral hemisphere. I shall assume that the former was the case.

The unreactive pupils are of little localizing value. They could have been Argyll-Robertson pupils or an iridoplegia due to damage of the third-nerve nuclei. Skew deviation was reported. This term applies to a lack of parallelism between the axes of the eyes so that one looks up and outward and the other is deviated down and inward. Skew deviation is usually associated with external ophthalmoplegias but occasionally with lesions of the cerebellum. The best interpretation here is that there was a disorganization of ocular movement at the level of the pons or midbrain.

Slight deviation of the head and eyes to the left requires a word of explanation. Stimulation of the aversive field of Brodmann's† Area 8 of the cerebral cortex causes turning of the head and eyes to the opposite side, and an epileptic focus does the same. Destructive lesions of these areas cause paralysis of contralateral gaze. Also destructive lesions just lateral to sixth nerve nucleus cause paralysis of gaze toward the side of the lesion, and usually a unilateral sixth-nerve palsy as well. I shall assume in this case that the head and eyes were turned to the left because of a disturbance in function at the level of the pons. The nystagmoid movements are an expression of the same disturbance. Here I am treading on dangerous ground, because they might have been due either to a pontine or a midbrain lesion or to a focus of irritation, that is, epilepsy, in the right frontal lobe.

The patient never actually moved her arms and legs except once when they were pricked with a pin. Was there paralysis for voluntary movement? One cannot say because she was comatose. Reflex withdrawal from a painful stimulus may be a spinal-reflex withdrawal and so does not give much assistance. Also, intermittent stiffening of the limbs could have been due to a transient release of postural mechanisms in the lower brain stem. Bilateral Babinski signs in a comatose person may only signify that the motor cortex is disordered as badly as the rest of the brain. I am unable to assume from all this that there was a quadriplegia due to a brain-

*Associate in neurology, Harvard Medical School; neuropathologist, Boston City Hospital.

†Brodmann, K. *Vergleichende Lokalisationslehre der Grosshirnrinde in ihren Prinzipien dargestellt auf Grund des Zellenbaues*. 334 pp. Leipzig: J. A. Barth, 1909.

stem lesion, although functionally there undoubtedly was a quadriplegia.

Deep coma lasting four days is always proof of severe brain disease. It can be due to the occlusion of the basilar or one of the other large cerebral arteries, to brain hemorrhage, to any of several metabolic diseases in which insufficient oxygen or glucose is sent to the brain or to repeated convulsions. Again, when interpreted physiologically, it is indicative of either a widespread and severe cerebral disorder or a disease in the vicinity of the thalamus and midbrain.

The temperature of 108°F., the pulse of 160 and the respirations of 50 are of interest. Often in midbrain and pontine lesions the temperature, pulse and respirations rise to great heights, possibly owing to a dysfunction of the heat-dissipating mechanism. Such could be the mechanism here. In comatose patients, however, pulmonary congestion and edema and bronchopneumonia are so frequent that these must always be given first consideration. With a leukocytosis and the x-ray films of the chest showing fine areas of increased density in the left lung field, bronchopneumonia is the likeliest explanation. In comatose patients the ground is always prepared for pulmonary infection, because of the disturbance of pulmonary vasomotor reflexes.

From this part of the discussion I come to the conclusion that we are dealing with a disease that diffusely involved the cerebrum and that the attacks of dizziness were either epileptic convulsions or minor apoplexy. Furthermore, in the last four days of life, there was an almost complete suppression of cerebral function due either to status epilepticus or to a lesion of the midbrain and pons.

Now let us search for the etiologic factor. The blood Hinton and Wassermann and the cerebrospinal-fluid Wassermann tests were positive. The spinal fluid showed increased cells, increased total protein and a first-zone colloidal gold reaction. This is the usual picture of general paresis, but it is not pathognomonic as was once believed. I have seen similar cerebrospinal-fluid findings in asymptomatic and other forms of neurosyphilis. The patient was said to have had congenital syphilis — a statement without proof. I do not believe that a congenital syphilitic patient would live until fifty-five before having symptoms. I know of no older patient than one who developed general paresis at twenty-nine. It is probable that this woman acquired syphilis in adult life, possibly after the birth of her children.

Of course, parietic neurosyphilis could have accounted for the whole picture. It is the obvious explanation of the personality changes, the curious dizzy spells and the nervous prostration. That parietic patients sustain injuries in such spells is well known, and old untreated patients often have subdural hematomas for this reason. These hematomas, now rarely seen, were once thought to be syphilitic.

But what about the final episode? On the basis of neurosyphilis there are two possible explanations: convulsions, since 50 to 60 per cent of parietics have them, and syphilitic basilar arteritis, with thrombosis and infarction. Although tempted at first to conclude that this patient merely went into coma and died of status epilepticus, I am compelled, because of the skew deviation, to assume a vascular lesion of the pons, namely, a thrombosis of the basilar artery with infarction of pons and midbrain. If the eyes were merely roving independently, as they often do in a comatose person, then this diagnosis is probably wrong.

CLINICAL DIAGNOSES

Cerebral hemorrhage.
Central-nervous-system syphilis.

DR. ADAMS'S DIAGNOSES

Thrombosis of basilar artery, with infarction of pons.
General paresis.
Bronchopneumonia.

ANATOMICAL DIAGNOSES

General paresis.
Bronchopneumonia.

PATHOLOGICAL DISCUSSION

DR. CHARLES S. KUBIK: Dr. Adams gave excellent reasons for thinking that this patient had thrombosis of the basilar artery. None was found, however, nor was there occlusion of any of the other main arteries. There was general paresis, with marked involvement of the cerebral cortex. There was also bronchopneumonia.

There was cloudiness of the arachnoid membrane. The convolutions were atrophied only slightly, and there was little enlargement of the lateral ventricles. Microscopically, the subarachnoid space and the perivascular spaces of the small cortical blood vessels were infiltrated with lymphocytes and plasma cells. In the cortex many nerve cells were degenerated; there were numerous rod-shaped microglial cells, and a proliferation of astrocytes. The capillaries and arterioles were prominent and appeared to be increased in number. There was a granular ependymitis of the fourth ventricle.

The findings were characteristic of general paresis. It is interesting that there was little generalized cerebral atrophy.

CASE 31012

PRESENTATION OF CASE

A forty-five-year-old woman was admitted to the hospital in coma.

Eight days prior to admission the patient complained of a headache, which became so severe the

following morning that she was forced to lie down. Shortly afterward she was found unconscious. The left side was completely paralyzed, there were slight twitchings of the right arm and leg, and the tongue was bleeding from an area where a small piece had been bitten out. The patient remained unresponsive until admission, except for two or three occasions when she said a few words and appeared to understand what was being said to her. The systolic blood pressure when she was found was said to have been 220; it varied between 140 and 180 afterward. The diastolic pressure was unknown, and there was no knowledge of previous hypertension.

The patient had had an "inflamed ovary" removed and an appendectomy nine and three years prior to admission, respectively. She had always bruised easily.

Physical examination revealed an unconscious woman, occasionally moaning and moving the arm and leg on the right but not on the left. There was a "mousey" odor to the breath. The skin and scleras had an icteric tinge. Numerous bruises, petechial hemorrhage and dilated capillaries were present over the extremities and to a lesser extent on the neck. The heart was slightly enlarged to the left, but there were no murmurs. A mass was palpable in the upper half of the epigastrium, rather more to the left than to the right of the midline. The pupils were of average size and equal and reacted slightly to light. The eyelids were closed, and the eyes were directed straight forward. The fundi were negative except for somewhat tortuous retinal arteries and a certain amount of arteriovenous nicking. The tendon reflexes were active and equal. There were extensor plantar responses bilaterally.

The temperature was 101°F., the pulse 76, and the respirations 16. The blood pressure was 160 systolic, 85 diastolic.

Examination of the blood revealed a red-cell count of 4,090,000, with 12.8 gm. of hemoglobin, and a white-cell count of 9600, with 75 per cent neutrophils, 10 per cent lymphocytes, 14 per cent monocytes and 1 per cent basophils. There was considerable polychromasia, platelets were present in fairly good numbers, and there were no toxic changes in the neutrophils. The clotting time was prolonged. Clot retraction was normal. The urine had a specific gravity of 1.026, with a ++ test for albumin and a sediment containing many red and white cells and occasional clumps of pus. The prothrombin time was 35 seconds (normal, 16 seconds). The blood sugar was 100 mg. per 100 cc., the serum nonprotein nitrogen 37 mg., and the van den Bergh 2.7 mg. direct, and 4.85 mg. indirect.

A roentgenogram of the chest revealed a generalized increase in the vascular markings. Examination of the abdomen showed an area of calcification in the left side of the pelvis that was thought to be a calcified fibroid and a calcified node in the right

lower quadrant. Examination of the skull was unsatisfactory because of the patient's condition.

A lumbar puncture on admission revealed grossly bloody and xanthochromic fluid under an initial pressure equivalent to 300 mm. of water. Its cell count was 10,200 red cells and 598 white cells, of which 513 were neutrophils. The protein was 264 mg. per 100 cc. One week later a second tap revealed clear yellow fluid with a total protein of 153 mg. per 100 cc.; no cell count was done. The spinal-fluid Wassermann test was negative.

The patient became progressively less responsive; the temperature fell to normal, and the pulse rate varied between 70 and 105. She was given 25 per cent, and later 10 per cent, dextrose in water intravenously, together with normal saline solution and vitamins. Four milligrams of Hykinone was administered daily. On the eleventh hospital day the patient began having generalized convulsive seizures, each lasting five to ten minutes. After two or three days, the seizures became milder and the patient began to improve. She became more responsive and began to talk a little. It was thought that a left homonymous hemianopsia could be demonstrated. The mental status continued to improve. On the thirty-fifth hospital day there was some voluntary motion of the left foot and hand. By this time the prothrombin time had gradually fallen to 28 seconds (normal, 20 seconds) and the van den Bergh was 0.6 mg. direct, and 0.9 indirect.

On the thirty-seventh hospital day the patient suddenly had a chill, followed by a rise in temperature to 102.6°F. There was considerable right costo-vertebral-angle tenderness. The urine sediment contained innumerable red and a few white cells, and a culture was positive for colon bacilli. A blood culture was also positive for colon bacilli. The neck again became stiff, and the patient lost consciousness. The white-cell count rose to 27,700, with 85 per cent neutrophils. Death occurred on the forty-sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JACOB LERMAN: Were the urine examinations done on catheter specimens?

DR. WYMAN RICHARDSON: They included at least one catheter specimen.

DR. LERMAN: I should like to comment on some of the highlights of the clinical findings. Apparently coma occurred a day or so after she became ill and after she developed headache. She had obvious left-sided paralysis, which points to a lesion on the right side of the cerebrum, but she had twitchings on the right, suggesting a more generalized involvement. She had convulsions at home and also while in the hospital. Those in the hospital were general in nature, not limited to one side. Unfortunately, nothing definite can be said about the presence or absence of hypertension. The reading before she came into the hospital suggests hypertension, but

those in the hospital do not. The changes in blood pressure may have been due to changes in spinal-fluid pressure.

There is a note saying that the patient bruised easily, but that really means nothing unless confirmed by physical findings or laboratory data. Many people give such a history, and it is not significant.

On physical examination certain findings, including a "mousey" odor to the breath, suggest liver disease. One can also observe the same odor in patients with severe infection, particularly those with septicemia. She certainly had jaundice and an enlarged organ, which I take to be the liver, primarily because of its location and also because of the presence of jaundice and a moderately elevated van den Bergh reaction. Apparently the left lobe of the liver was enlarged, since the mass was to the left of the midline. Left-lobe enlargement of the liver suggests syphilis. No mention is made of the blood Hinton test, and there is no evidence of syphilis elsewhere, the spinal-fluid Wassermann test being negative. Consequently, syphilis need not be considered.

She had bruises, petechial hemorrhages and dilated capillaries, which may be manifestations of a hemorrhagic disease, such as thrombocytopenic purpura or symptomatic purpura, or of septicemia, such as blood-stream infection with the meningococcus. In the presence of liver disease confirmed by a prolonged prothrombin time, however, one can adequately explain these signs.

The tendon reflexes were active and equal. That is strange because from the description one would expect inequality. The right arm moved; the left arm did not. Bilateral extensor plantar reflexes also indicated generalized injury to the brain rather than localized injury, which we assumed from the description of the patient. Is it possible that she had not yet developed complete evidence of a unilateral cerebral hemorrhage? Seven days had passed, and one would expect complete manifestation of the injury by that time. Since she did have positive Babinski signs, then the evidence of injury was complete. It is hard to reconcile the various reflex changes with a unilateral cerebral lesion. One may assume generalized injury to the brain, such as could be produced by diffuse hemorrhage, or, in addition to a right cerebral lesion, a previous injury to the left cortex, about which we know nothing.

She had slight anemia and polychromasia, the latter indicating excessive stimulation of bone marrow. The number of platelets was normal, which rules out idiopathic thrombocytopenic purpura. The elevated prothrombin time and van den Bergh values fit in with other evidence of liver disease. The urinary findings indicate pyelonephritis or possibly diffuse hemorrhage involving the kidney substance.

DR. RICHARDSON: I ought to give you additional information. The patient had to be on constant drainage.

DR. LERMAN: Then the urinary findings are not of much value, and I shall have to disregard them.

The lumbar puncture yielded a spinal fluid containing a lot of blood, including old blood, as evidenced by the xanthochromic fluid; the white-cell count was high, consistent with irritation produced by the bleeding, and the Wassermann test was negative. There is no mention of organisms; presumably none were found.

The patient lost ground for a while and then improved. The left homonymous hemianopsia points to a lesion posterior to the chiasm on the right side in the optic radiations going to the occipital lobe. This is consistent with the left-sided paralysis that the patient had.

She then had generalized convulsions, some temporary improvement in the prothrombin time and the van den Bergh reaction and, finally, a colon-bacillus septicemia.

It is difficult for me to put all these findings together. Certainly one can rule out thrombocytopenic purpura as the etiologic factor. Could she have had symptomatic purpura as a result of infection? There is not enough evidence in the early part of the history to indicate a general infection. The problem is to explain the development of coma, which was undoubtedly due to extensive cerebral hemorrhage, including subarachnoid hemorrhage, in addition to at least one major lesion on the right side to account for the left-sided paralysis and the left homonymous hemianopsia. One can arrive at this syndrome by various routes.

First, she may have developed jaundice from acute hepatitis, toxic or infectious in nature, which resulted in an elevated prothrombin time and a tendency to diffuse hemorrhage in the skin and brain. Since the process was rather acute and fulminating, the liver damage may have been in the nature of acute or subacute yellow atrophy. The colon-bacillus infection must then be considered as a terminal event, perhaps due to the indwelling catheter, or to a long-standing pyelonephritis that merely spread terminally.

Second, the patient may have had a serious infection with septicemia, type unknown. It might have been a colon-bacillus infection that was not recognized at first. The septicemia produced jaundice and the hemorrhagic tendency. A possible subheading under this mechanism is that the absorption of hemolyzed blood from the sites of hemorrhage caused plugging of bile capillaries sufficient to produce jaundice. In either case, the jaundice did not play any role of importance. Death was due to recrudescence of the original infection.

Third, the patient may have had bacterial endocarditis due not to *Streptococcus viridans* but to the

colon bacillus. Such an infection would explain many of the central-nervous-system findings and even the jaundice. On the other hand, there is no history of pain, which is so frequently associated with the embolic phenomena of bacterial endocarditis, unless, of course, cerebral embolism occurred first and knocked out all conscious sensations. There are no findings in the heart to point to endocarditis. The absence of any information regarding blood cultures until the final culture was obtained steers one away from a diagnosis of endocarditis.

One must also think of such rare conditions as hepatoma, with cerebral manifestations resulting from metastatic involvement of the cerebrum. This would not explain, however, the tendency to skin hemorrhages, unless there was an associated cirrhosis. Rupture of an aneurysm on the right side of the brain could explain all the cerebral findings but not the peripheral findings, such as the tendency to hemorrhage in the skin, and the liver damage.

Thus I am right back to my first thought: namely, this was a patient with jaundice due to acute hepatitis, probably subacute yellow atrophy. The hemorrhagic tendency resulting therefrom then produced cerebral vascular bleeding, diffuse throughout the brain and subarachnoid space, but including one major lesion on the right side. In addition one might suppose that the colon bacilli would localize in the spinal fluid, and also in the areas of cerebral damage.

DR. RICHARDSON: I want to give Dr. Lerman more bits of evidence. In the first place, the capillary dilatation was not diffuse, but true spider-angioma telangiectasis. This was more striking than in any patient I have ever seen — small central red spots with lines radiating in a characteristic spider design, most marked over the chest and abdomen but also present on the arms and elsewhere. I did not tumble to this the first night I saw the patient, but the next morning it seemed important. At that time I also noticed jaundice and the mousey odor to the breath. I thought it was all due to hepatic failure, and in the note I wrote, I said that she had primary liver failure with a bleeding tendency, causing some type of bleeding lesion in the brain. Later I discovered that for many years she had had a high alcoholic intake; in fact, one of the surgeons who had operated on her previously reported that she had had at that time a cirrhosis of the liver. My thought was that she had cirrhosis of the liver with superimposed acute hepatitis and cerebral hemorrhage. I thought the latter was subarachnoid and possibly due to a congenital aneurysm, with more bleeding than normally would have been expected. I did not see the patient at the very end, but I believe that the second episode meant that she had another hemorrhage.

A PHYSICIAN: What about the mass in the epigastrium?

DR. RICHARDSON: I thought that it was the liver, but not entirely the left lobe.

DR. LERMAN: I did not mean to indicate that the mass was entirely due to left-lobe enlargement, but certainly a prominent left lobe points toward syphilis. The additional history indicates extensive chronic liver disease rather than an acute episode of liver disease, and confirms my supposition that the hemorrhagic tendency was due to liver disease. Another possibility, which I think I can dismiss, is the development of a hepatoma in a cirrhotic liver. She could have had a hepatoma with metastases to the brain, and coma could have been produced by hemorrhage into one or more metastases.

DR. JOSEPH C. AUB: Hepatoma rarely metastasizes to the brain. There are a few cases in the literature, but they are unusual.

DR. LERMAN: I thought that a hepatoma metastasized to almost any organ.

DR. AUB: Sometimes to lung, and sometimes brain; but it is rare.

DR. LERMAN: I admit that it is unusual, but I was trying to find one diagnosis to cover all the findings. I shall have to stick to my original diagnosis of hemorrhagic tendency from liver disease.

DR. RICHARDSON: We considered hepatoma in the beginning on the basis of the mass and also because of the polychromasia, but I finally explained the latter in the way Dr. Lerman did, that is, as due to hemorrhage, and discarded the idea of hepatoma.

CLINICAL DIAGNOSES

Cerebral hemorrhage.
Alcoholic cirrhosis of liver.
Acute hepatitis.
Septicemia (colon bacillus).

DR. LERMAN'S DIAGNOSES

Cerebral hemorrhage, diffuse and right cerebral.
Subarachnoid hemorrhage.
Portal cirrhosis.
Acute hepatitis.
Septicemia (colon bacillus).
Pyelonephritis?

ANATOMICAL DIAGNOSES

Cerebral hemorrhage, old: right temporal lobe.
Cerebellar hemorrhage, recent.
Cerebral infarction, right frontal and parietal, old.
Toxic cirrhosis of liver.
Septicemia (colon bacillus).
Acute pyelonephritis.
Bronchopneumonia, with abscess formation.
Petechieae of skin, gastrointestinal tract, pleura, epicardium and endocardium.
Jaundice.
Operations: appendectomy and right oöphorectomy, old.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Before Dr. Kubik tells us what was found in the brain, I shall say

that there was cirrhosis of the liver. It did not look like the ordinary alcoholic type. The nodules varied in size tremendously. The usual case of alcoholic cirrhosis shows uniformly small nodules. These suggested the healed atrophy or toxic type of cirrhosis. We found no evidence of acute hepatitis.

DR. RICHARDSON: She had, however, been in the hospital a long time.

DR. LERMAN: Forty-six days.

DR. CASTLEMAN: She had, as you know, a colon-bacillus septicemia and numerous abscesses to the kidney. I do not know whether the abscesses developed after her admission to the hospital, but she probably had some degree of pyelonephritis before she came in. The lungs were diffusely studded with areas of bronchopneumonia that had broken down and formed abscesses. She had a great deal of infection, which may have accounted in part for the jaundice; that is, the jaundice may have been due to the combination of overwhelming infection and a poorly functioning liver. I do not believe that the liver disease itself was responsible for that amount of jaundice.

DR. RICHARDSON: If you had seen her when she came in, it might have altered your opinion. The liver was acutely involved. She was given tremendous amounts of glucose intravenously.

DR. CASTLEMAN: Did the liver shrink?

DR. RICHARDSON: I cannot remember. I do not see any note to that effect but believe that it did. She began to improve and everyone felt encouraged, and then she had a sudden episode and went down hill.

DR. CHARLES S. KUBIK: Most subarachnoid hemorrhages, as you all know, are due to ruptured aneurysms. We did not find any aneurysm in this case. There was an area of infarction in the right frontal lobe. This probably contributed only slightly to the symptomatology. The main lesion was an old hemorrhage in the right temporal lobe. This hemorrhage, measuring 8 cm. in length, extended practically the whole length of the temporal lobe. It was surrounded by a firm connective-tissue capsule about 0.5 mm. in thickness. There was also a recent hemorrhage in the cerebellum, which unquestionably accounted for the episode that occurred shortly before the patient died and was probably the chief cause of death. It had broken

through into the subarachnoid space. There was but little arteriosclerosis. I am not sure whether the older hemorrhage had leaked into the ventricle or into the subarachnoid space, or into both.

DR. CASTLEMAN: Do you think that this was the usual form of cerebral hemorrhage? May it not have been due to jaundice?

DR. KUBIK: I do not know. I have seen three cases with severe jaundice and cerebral or subarachnoid hemorrhage. The two with cerebral hemorrhages came to autopsy; the one who had a subarachnoid hemorrhage is still living.

DR. CASTLEMAN: This patient's heart weighed about 400 gm., which is not particularly large. Do you think that she had had hypertension in the past?

DR. RICHARDSON: When the story was given to me I was inclined to doubt it.

DR. CASTLEMAN: If we knew that she had not had hypertension, we could blame the hemorrhage on the jaundice.

DR. RICHARDSON: There was just the one reading, taken shortly before she entered the hospital. At the time of one of her previous operations there was no hypertension.

DR. KUBIK: The systolic reading of 220 was obtained after onset of the first hemorrhage, and the elevation might have resulted from increased intracranial pressure.

DR. RICHARDSON: I have had personal experience with three patients with severe liver damage accompanied by severe cerebral bleeding of one sort or another. One had a subdural hematoma that was successfully operated on; the hemorrhage may have been due to trauma, although the amount of bleeding was more than one would expect. At this moment there is a patient in the hospital with severe alcoholic cirrhosis who has probably had some cerebral bleeding. My interpretation is that the bleeding is due to prothrombin lack, although there must be something to precipitate the bleeding.

DR. CASTLEMAN: Is it not also true that a person with as large a cerebral hemorrhage as this would usually have died before there was a chance for a second episode.

DR. KUBIK: Yes; massive cerebral hemorrhages are practically always rapidly fatal, the patient rarely surviving more than a few days.

NAVAL MEDICAL OFFICERS

Although the Army of the United States has indicated that its need for medical officers is, for the moment, covered by recent graduates from medical schools who have completed their internships and residencies, an urgent demand for such officers in the United States Navy, whose personnel and activities are constantly increasing, still continues. As noted in a letter published elsewhere in this issue of the *Journal*, the physical requirements for the Navy Medical Corps have been lowered, the age limit has been increased and waivers may be obtained for certain disqualifying physical defects. Undoubtedly the applications of

many physicians were refused because of one of these reasons. Each one of these men, as well as others who believe that their contributions to the war effort would be greater in a service capacity than in civilian practice, should respond to this appeal.

A SURGEON ON WAR AND PEACE

COLONEL ELLIOTT C. CUTLER, chief consultant in surgery, Army of the United States, European Theater of Operation, and Moseley Professor of Surgery, Harvard Medical School, delivered on May 6, 1944, at St. John's College, Cambridge, England, the Linacre Lecture on the subject "A Surgeon Looks At Two Wars." Colonel Cutler's lecture, in abridged form, has appeared as the leading article in the September 30 issue of the *Lancet*.

The comparison between the types of injuries sustained in this war and their treatment and those of twenty-five years ago is interesting; more important is the apparently considerable increase in psychiatric casualties over those of 1916-1918 despite a more rigid screening at the source, and the theories advanced to explain this experience. Chief among these explanations rank an easier discipline in our army of today, leaving an avenue of escape open for the battle-weary soldier, inferior leadership by subaltern officers, and a loss of self-sufficiency and independence in a country where overpaternalism has softened the population.

In particular, Colonel Cutler emphasizes the military value of hate in carrying a war through to its successful conclusion; he points out that it is a military fault of the English and Americans that they are naturally peace-loving and have as yet found little cause for holding such a personal grudge against the Germans as have the Russians. This hatred we have had cause to develop against the Japanese, and the Japs we are able to hunt down with relentless fury, for their atrocities have been committed against ourselves.

Future opportunities for Germany to fling herself at the throats of civilized mankind must be denied, and Colonel Cutler closes his lecture on the note that those who make the peace must this time be those who have been to war and know what it

means. It is expressly stated that war must be waged in hate, and it is implied that hate must not be forgotten when the peace is made.

In the same issue of the *Lancet* is one of the sanest and most temperate editorials that it has been our fortune to read — an editorial that bespeaks the innate fair-mindedness of the British nation. We are reminded that this war is not between men and a different species, but between men and men, in whom all the human elements are mixed. True, our adversaries have been led into intolerable deeds by their psychologic immaturity, but "five years have not changed our opinion that a peace of understanding has more permanence than a peace of passion."

"The young men who now command our thoughts and bear our hopes," the editorial continues, "are often heroes but seldom fanatics; and for our part we should say that one of their greatest achievements has been to combine military resolution with an objective attitude toward the enemy."

An attempted destruction of Germany will sow the seeds of hate and prepare for a future harvest of calamity. Our only hope is in a modeling of civilization, to help young Germans "feel it an adequate purpose in life to rebuild out of the ruins the Germany of Kant and Goethe and Beethoven — to whom we might add Virchow, Koch and Ehrlich, or others according to taste."

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

ALLEN — Gardner W. Allen, M.D., of Boston, died July 12. He was in his eighty-ninth year.

Dr. Allen received his degree from Harvard Medical School in 1882. He was formerly professor of genitourinary surgery at Tufts College Medical School, and surgeon in the Genitourinary Department of the Boston Dispensary. He was a member of the American Association of Genito-Urinary Surgeons, Massachusetts Historical Society, American Antiquarian Society, Naval Historical Foundation, American Historical Association and the Military Historical Society of Massachusetts.

DAWSON — Raymond J. Dawson, M.D., of Methuen, died November 20. He was in his thirty-ninth year.

Dr. Dawson received his degree from McGill University Faculty of Medicine, Montreal, in 1932. He interned at the Lynn Hospital and Montreal General Hospital, and had practiced in Methuen from 1934 until entering the Army of the United States as a lieutenant in the Medical Corps, from which he was eventually honorably discharged. He was a fellow of the American Medical Association.

His widow, his parents and three brothers survive.

HAWES — Edward E. Hawes, M.D., of Hyannis, died November 30. He was in his eighty-third year.

Dr. Hawes received his degree from the University of Vermont College of Medicine in 1886. He was on the staff of the Cape Cod Hospital.

OSSEN — Emil Z. Ossen, M.D., of Quincy, died December 16. He was in his thirty-ninth year.

Dr. Ossen received his degree from State University of Iowa College of Medicine, Iowa City, in 1931. He was staff physician of the Norfolk County Hospital from 1932 to 1937. He was visiting physician at the Beth Israel Hospital and on the staff of the Quincy City Hospital and the Milton Hospital. He was a fellow of the American Medical Association.

His widow, a son and a daughter survive.

SANBORN — Byron Sanborn, M.D., of Topsfield, died December 20. He was in his seventy-first year.

Dr. Sanborn received his degree from Dartmouth Medical School, Hanover, New Hampshire, in 1900. He served as associate medical examiner for one district of Essex County from 1930 to 1939. He had also served as examining physician for Topsfield public schools and was town medical adviser. He was a fellow of the American Medical Association.

His widow and a son survive.

YOUNG — Evangeline W. Young, M.D., of Framingham, died December 20. She was in her seventy-first year.

Dr. Young received her degree from Tufts College Medical School in 1906. She practiced medicine in Boston until 1934. She was a former member of the Massachusetts Medical Society.

A brother survives.

COMMENT

Poliomyelitis during November showed the expected marked drop in number of cases, there being only a little more than a third of the previous month's cases. Diphtheria, although at a comparatively low point as compared with the levels ten or fifteen years ago, was nonetheless twice the seven-year median for November. There is still plenty of need for stressing immunization.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Arlington, 2; Ashfield, 1; Boston, 5; Brockton, 1; Colrain, 1; Conway, 1; Dalton, 1; Easton, 2; Fort Devens, 1; Groveland, 2; Haverhill, 1; Holyoke, 1; Lexington, 2; Marlboro, 1; Melrose, 1; Middleboro, 2; New Bedford, 1; Pittsfield, 7; Rockland, 1; Williamstown, 1; total, 55.

Diphtheria was reported from: Ayer, 1; Boston, 2; Danvers, 1; Foxboro, 1; Framingham, 1; New Bedford, 3; Peabody, 2; Somerville, 15; Whitman, 1; Worcester, 3; total, 28.

Dysentery, bacillary, was reported from: Beverly, 2; Boston, 5; Dedham, 1; Everett, 1; Fall River, 4; Lawrence, 1; Lynn, 1; North Andover, 3; Somerville, 1; Stoneham, 1; Winchester, 2; Worcester, 2; total, 24.

Encephalitis, infectious, was reported from: Newton, 2; Quincy, 1; total, 3.

Malaria was reported from: Boston, 2; Camp Edwards, 8; Fort Devens, 16; Cushing General Hospital, 16; Haverhill, 4; Hingham, 1; Woburn, 1; West Bridgewater, 1; Worcester, 1; total, 50.

Meningitis, meningococcal, was reported from: Arlington, 1; Boston, 9; Cambridge, 2; Canton, 1; Chelsea Naval Hospital, 1; Easton, 1; Everett, 1; Falmouth, 1; Framingham, 1; Hardwick, 1; Lowell, 2; Lynn, 1; Medford, 1; Newton, 2; Palmer, 1; Quincy, 2; Watertown, 1; Webster, 1; Weymouth, 1; total, 31.

Meningitis, Pfeiffer-bacillus, was reported from: Lawrence, 1; Springfield, 1; Wellesley, 1; total, 3.

Meningitis, pneumococcal, was reported from: Boston, 1; Cambridge, 1; Springfield, 1; total, 3.

Meningitis, other forms, was reported from: Boston, 2; Milford, 1; Needham, 1; total, 4.

Meningitis, undetermined, was reported from: Auburn, 1; Worcester, 1; total, 2.

Salmonella infections were reported from: Framingham, 1; Medford, 1; Salem, 1; Wellesley, 1; total, 4.

Septic sore throat was reported from: Boston, 10; Holyoke, 2; Marion, 1; Newton, 1; total, 14.

Tetanus was reported from: Beverly, 1; North Attleboro, 1; Quincy, 1; total, 3.

Trichinosis was reported from: Boston, 1; total, 1.

Typhoid fever was reported from: Rehoboth, 1; total, 1.

Undulant fever was reported from: Bridgewater, 1; Lawrence, 1; Mansfield, 1; Somerville, 1; Southbridge, 1; total, 5.

MISCELLANY

NOTE

The following physicians were accepted into fellowship in the American College of Surgeons during 1944:

MASSACHUSETTS: Boston — E. L. Carey, P. W. Hugenberger, A. C. Kallan, H. G. Lee, R. E. Mabrey, D. O. McKee, J. J. Michelsen and L. H. Nason; Brookline — J. F. Conway, C. J. Duncan and H. C. Rosen; Brockton — S. F. Peterson; Cambridge — R. W. Smith; Fall River — D. F. Gallery; Norwell — Ralph Heifetz; Norwood — D. J. Collins; Salem — F. P. Morse, Jr.; Walpole — G. O. Garcelon; Westfield — D. R. Hayes and J. J. Tomasi; Worcester — E. E. Fipphen, E. J. Medden and Adolph Meltzer.

NEW HAMPSHIRE: Epping — W. C. Montgomery; Manchester — D. J. Sullivan and S. W. Yudicky; Nashua — Philip McQuستن.

CORRESPONDENCE

NEED FOR NAVAL MEDICAL OFFICERS

To the Editor: The daily casualty reports emphasize the urgent need for medical officers, and the procurement of doctors for the United States Naval Reserve remains a number one priority at this time. A concentrated effort is being made to obtain approximately 3000 physicians in order to increase the efficiency of the present medical forces.

Doctors on the home front are sacrificing many peacetime pursuits in professional and social fields in order to preserve existing medical standards. It is evident, however, that a disproportion of medical personnel exists in many communities throughout the country. In some areas, the number of physicians exceeds the demands, whereas in others there is

a definite shortage. The problem is largely one of redistribution. Each doctor should reach a conscientious decision whether or not he can make a greater contribution in a direct military capacity.

Physical requirements for the Navy Medical Corps have been modified considerably since the beginning of the war. Doctors may now be accepted up to the age of sixty. Those in the older age groups are assigned to naval hospitals, dispensaries, the Veterans' Administration and other naval activities ashore. Organic physical defects continue to be disqualifying, but waivers can be granted for a variety of conditions that were formerly unacceptable.

Without making any definite commitment, applicants may be interviewed at this office without prior appointment on any weekday. Additional pertinent information will be furnished, and individual problems can be discussed.

H. S. GLINDEN, Commander (MC), U.S.N.R.
Senior Medical Officer

Office of Naval Officer Procurement
150 Causeway Street
Boston 14

THE MACHINE AGE

To the Editor: Something grim has happened to society since the opening of the industrial revolution about one hundred and seventy years ago. Much of it should be the concern of the medical sciences.

For several generations there has been abroad in the world the notion that character, culture and contentment can come through the multiplication of machines. This illusion has had a large part in developing the emotions and social unrest which now finds us fighting a second world war.

When the excessive mechanization of society creates such fantastic and swiftly changing environments that distortion and deterioration of standards and values result, man's limited biologic equipment (including his mental, moral and spiritual potentialities) is unequal to the task of making normal peaceful adjustments.

Is this the law of diminishing cultural returns?

What, if anything, can the medical profession do to interpret and correct this pathology?

A. E. P. ROCKWELL, M.D.

241 Grafton Street
Shrewsbury, Massachusetts

BOOK REVIEWS

Tuberculosis of the Ear, Nose and Throat. By Mervin C. Myerson, M.D. 8°, cloth, 291 pp., with 88 illustrations. Springfield, Illinois: Charles C Thomas, 1944. \$5.50.

Dr. Myerson has had an unusual opportunity to study tuberculosis of the upper respiratory passages at the Sea View and Metropolitan hospitals in New York City. In this book, he draws on his vast experience with more than 10,000 cases for the many salient facts that are presented.

Inasmuch as tuberculosis of the larynx is the lesion most frequently encountered in practice, over half the book is devoted to this disease. Treatment is covered in detail, and the reviewer is in full accord with the methods that are considered beneficial and those that should be discarded. Other chapters briefly consider tuberculosis of the nose, ear, oral cavity, tongue, pharynx and esophagus. Finally, he gives full consideration to tuberculosis of the trachea and bronchi. Recent concepts of tuberculosis of the bronchi, including etiology, diagnosis and pathology, are fully discussed, although its treatment still awaits further study and experience. The illustrations and drawings are excellent and help considerably in visualizing the pathology.

The author is outspoken in his opinions, which, on the whole, are based on sound scientific principles. This book will be invaluable to otolaryngologists, as well as to all men interested in the problem of tuberculosis.

Intravenous Anesthesia. By R. Charles Adams, M.D., C.M., M.S. (Anes.). 8°, cloth, 663 pp., with 75 illustrations. New York City: Paul B. Hoeber, Incorporated, 1944. \$12.00.

With the ever-widening fields of usefulness of intravenous anesthetics, this book is most timely. Dr. Adams is to be congratulated on the comprehensive manner with which he

has treated this subject. The book should be read by every anesthesiologist, and it will make a useful addition to any surgical library.

The chapters dealing with the history of intravenous apparatus, methods and agents are excellent, being particularly valuable to those interested in the history of medicine. The fact that the historical aspects of intravenous methods are so well covered does not mean that the practical side of the subject has been neglected. About two thirds of the book are devoted to the barbituric acid derivatives, this being the group of drugs that has proved the most practical for intravenous anesthesia.

The chapter on the technic of intravenous injection is especially to be recommended. It contains many suggestions that will prove helpful to anyone who is called on to do venipuncture, whether or not for the administration of an anesthetic agent.

The appropriateness of the chapter on analeptics is well stated in its opening sentence, "It seems appropriate after detailed discussion of the depressant drugs such as the derivatives of barbituric acid, particularly their effect on respiratory function, to consider, at least briefly, the value of respiratory stimulants and analeptics in combating the depressing effects of these drugs."

The final chapter, which discusses intravenous anesthesia for military surgery, is timely, and Dr. Adams was wise in covering this aspect of the subject in a separate and final chapter, thus making for a more general and prolonged usefulness of the book.

The bibliographies after each chapter are extensive.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Allergy in Practice. By Samuel M. Feinberg, M.D., associate professor of medicine and chief of the Division of Allergy, Northwestern University Medical School. With the collaboration of Oren C. Durham, chief botanist, Abbott Laboratories. Chicago: The Year Book Publishers, Incorporated, 1944. \$8.00.

This new work on allergy has been written for the benefit of not only allergists but also of practicing physicians. The arrangement of the book is practical, since the clinical parts of the text are set in type of normal size, and controversial and other material are in smaller type. In the work are embodied Dr. Feinberg's investigations on fungi allergy, as well as the thirty years' experience of Dr. Durham on pollens and pollen allergy. In addition to asthma and hay fever, many other allergies, including sensitivity, are adequately discussed. Diagnosis and treatment are especially emphasized.

The Dental Treatment of Maxillo-Facial Injuries: With supplementary material on cases and techniques. By W. Kelsey Fry, M.C., M.R.C.S., L.R.C.P., L.D.S., R.C.S. (Eng.), consulting dental surgeon to the Royal Air Force, consulting dental surgeon to the Ministry of Health, and dental surgeon to Guy's Hospital; P. Rae Shepherd, L.D.S., R.C.S. (Eng.), dental surgeon, East Grinstead Maxillo-facial Unit; Alan C. McLeod, D.D.S. (Penn.), B.Sc. (dent.) (Toronto), L.D.S., R.C.S. (Eng.), dental surgeon, East Grinstead Maxillo-facial Unit; and Gilbert J. Parfitt, M.R.C.S., L.R.C.P., L.D.S., R.C.S. (Eng.), dental surgeon, East Grinstead Maxillo-facial Unit. With a foreword by Professor F. R. Fraser, M.D., F.R.C.P., director general, Emergency Medical Service, and a section on fractures of the middle third of the face by A. H. McIndoe, M.S., F.R.C.S., F.A.C.S., consulting plastic surgeon to the Royal Air Force, and surgeon-in-charge, East Grinstead Maxillo-facial Unit. 8°, cloth, 434 pp., illustrated. Philadelphia: J. B. Lippincott Company, 1944. \$6.50.

This is an American edition of an English work published in two parts and comprising lectures and demonstrations given to members of the English armed forces at East Grinstead Maxillo-facial Centre. The purpose of this work

is to provide simple instruction in the treatment of injuries of the face as it concerns the dental surgeon.

The Romance of Medicine: The story of the evolution of medicine from occult practices and primitive times. By Benjamin L. Gordon, M.D., attending ophthalmologist, Shore Memorial Hospital, Somers Point, New Jersey, and Atlantic County Hospital for Tuberculosis, Northfield, New Jersey. 8°, cloth, 624 pp., with 145 illustrations. Philadelphia: F. A. Davis Company, 1944. \$5.00.

This new work on the history of medicine emphasizes primitive medicine and its relation to the development of modern medicine. The author believes that modern medicine and modern customs are truly an evolutionary development of ancient animistic beliefs, and he has attempted to present a readable but comprehensive account of the ideas alike in the state of health and disease of our savage, semicivilized and civilized ancestors: what their thought was concerning embryology and anatomy, their ideas of the controlling forces governing the human mechanism, their concepts of the mind and soul, and the role it was assumed to play in the human economy.

NOTICES

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held at the Peter Bent Brigham Hospital on Tuesday, January 9, at 8:15 p.m.

LAWRENCE CLINIC

The Lawrence Clinic has recently been reorganized. Captain G. F. Clark, U.S.N. (retired) will direct the Clinic, and arrangements have been made with the Executive Committee of the Lawrence General Hospital, composed of Drs. Harold R. Kurth, Rolf C. Norris, John J. Hartigan, Z. William Colson, Richard J. Neil and Percy J. Look, whereby the staff of the Lawrence General Hospital will act as the staff of the Lawrence Clinic. When the work of the Clinic increases and more physicians and dentists become available, the program of services will be modified accordingly.

NATIONAL CONFERENCE ON MEDICAL SERVICE

Postwar distribution of medical care will be the theme for the nineteenth annual session of the National Conference on Medical Service to be held in the Red Lacquer Room of the Palmer House, Chicago, on Sunday, February 11, 1945. Medical legislation, physical-fitness programs, the rehabilitation of veterans, the latest word from the Washington front and the relation between labor and farm groups and medicine are among the topics to be discussed by nationally known speakers. Also listed on the program will be an open discussion on prepayment medical plans, the principal advantages and defects of both service and indemnity types of insurance being presented. Congressman Arthur L. Miller, of Nebraska, author of the Miller Bill to unify certain health services, is to be among the speakers. All members of the American Medical Association are invited to attend. Detailed programs of the conference are now ready and may be obtained by writing to Cleon A. Nafe, M.D., secretary, National Conference on Medical Service, 822 Hume Mansur Building, Indianapolis 4, Indiana.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JANUARY 11

FRIDAY, JANUARY 12

*9:00-10:00 a.m. Cancer of the Pancreas and Ampulla Relative to Diagnosis and Resection. Dr. Richard B. Cattell. Joseph H. Pratt Diagnostic Hospital.

10:50 a.m. Malignant Tumors. Dr. George E. Morris. (Postgraduate clinics in dermatology and syphilis.) Dowling Amphitheater, Boston City Hospital.

SATURDAY, JANUARY 13

*10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, JANUARY 15

*12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

BACTEROIDES INFECTIONS*

An Analysis Based on a Review of the Literature and a Study of Twenty Cases

WILLIAM E. SMITH, M.D.,† AND MARIAN W. ROPES, M.D.‡

BOSTON

THE gram-negative anaerobic bacilli that do not bear spores have been grouped together in a genus to which the name "Bacteroides" has been assigned.¹ There are many reports of human infections caused by Bacteroides, but the occurrence of such cases is not widely appreciated. During the last four years, 20 cases have been seen at this hospital (Table 1). On the basis of cases reported in the literature and those seen here, an attempt will be made to describe the clinical aspects of these in-

fections, with the purpose of calling attention to the various conditions in which Bacteroides infection should be suspected.

The classification of species within the genus Bacteroides is discussed at the end of this paper. It should be noted that the Bacteroides do not include the anaerobic bacilli of the Dialister and Fusiformis groups, which are at present preserved as separate genera,¹ the one because of the small size of the organisms composing it, the other because of the characteristic pointed shape of its members. Detailed data concerning the many known strains of Bacteroides have been compiled by Weinberg, Nativelle and Prévot.⁵ Recently, Dack⁶ has published a review of the Bacteroides of medical importance. In studies of strains recovered in this laboratory, a form of bacterial reproduction different from simple fission and associated with the production of anaerobic pleuropneumonia-like colonies as variant growth forms (L-type variation) has been encountered in certain instances. These studies have been presented elsewhere.⁷⁻¹¹

TABLE 1. *Bacteroides* Infections Seen at the Massachusetts General Hospital, 1939-1943.

TYPE OF INFECTION	NO. OF CASES	RESULT

BACTEROIDES SEPTICEMIAS

Bacteroides septicemias usually arise following throat infections, otitis media and mastoiditis, surgery or infections of the large bowel or genitourinary tract and war wounds. Etiologically, these septicemias may be divided into two groups. The first and more frequent are the cases caused by the *Bacteroides funduliformis* group of organisms, markedly pleomorphic bacilli characterized by the formation of large bodies (spheres) and filaments on cultivation in artificial mediums. These cases frequently develop metastatic abscesses and carry a high mortality. Pus from the abscesses is usually thick, greenish yellow and somewhat foul but not putrid. The organisms are present in large numbers and may readily be detected in smears as small gram-negative bacilli. The second, and less frequent, group of cases are caused by *Bact. fragilis* or other nonpleomorphic Bacteroides. These cases usually run a less fulminating course, with less tendency to

‡Associate physician, Massachusetts General Hospital; assistant in medicine, Harvard Medical School.

the formation of metastatic abscesses. Their prognosis is less grave, only 3 of 8 reported cases having had a fatal termination.¹²

Following Throat Infections

Excellent clinical and pathologic studies of *Bact. funduliformis* septicemias following throat infections have been presented by Lemierre¹³ and by Pham Huu Chi.¹⁴ Among 16 cases, 13 were fatal. The close similarity of Case 1 of the present report and that recently described by Brown, Williams and Herrell¹⁵ to the cases reported by these authors is striking. The cases usually occur in previously healthy persons between twenty and thirty years of age. The onset is sudden, with a chill and high fever, usually on the fourth or fifth day of a pharyngitis, tonsillitis or peritonsillar abscess. The local infection in the throat may appear mild or severe. Chills may recur frequently. Multiple abscesses in the lungs, liver and joints and a serous or purulent pleurisy may develop. Jaundice is frequently observed. A moderate anemia, with a red-cell count of 3,800,000 to 2,800,000, and a polymorphonuclear leukocytosis, with a white-cell count of 14,000 to 22,000, are encountered. In acute cases death may follow within a week.

Joint metastases occurred in 8 of 12 cases, chiefly involving large joints, such as the elbow (4 cases) scapulohumeral (4 cases), knee (3 cases) and hip (1 case).¹⁴ Except for the sternoclavicular joint, which was involved in 2 cases, the smaller articulations were spared. Recovery without ankylosis occurred in 1 case following incision and drainage of two joints and a spontaneous resorption of the effusion in a third. *Bact. funduliformis* was seen in smears of the pus obtained from these joints and was recovered in cultures. Joint involvement — of the hip — was also seen in 1 of the 2 fatal cases of septicemia with *Actinomyces necrophorus* reported by Cunningham.¹⁶ According to Dack,⁸ this organism may be identical with *Bact. funduliformis*.

Following Chronic Otitis Media and Mastoiditis

Bacteroides septicemias arising from chronic otitis media and mastoiditis have been reported. Of 2 cases due to *Bact. fragilis*, 1 resulted in recovery.¹⁷ In 1 case due to *Bact. funduliformis* there developed osteomyelitis of the femoral head with abscess in the hip joint.¹⁸ This patient recovered after drainage of the joint and sequestrectomy of the femoral head. It could not be determined whether the infection had arisen in the bone and extended into the joint or vice versa. From a case reported by Rist,¹⁹ it appears that *Bacteroides* infection of a joint may destroy the cartilage and invade the bone or spread through the synovial tissues to present itself as a subcutaneous abscess.

Following Surgery of Large Bowel

A series of *Bact. funduliformis* septicemias following surgery of the large bowel has been reported from the Mayo Clinic. In 1934, Beaver, Henthorne and Macy²⁰ described a fatal case following colostomy for carcinoma of the rectum. In the same paper they described another case, which, in the light of Lemierre's cases,¹³ appears to have originated from an upper respiratory infection. In 1937, Dixon and Deuterman²¹ reported 5 proved cases and 1 presumptive case, all of which followed operations for carcinoma of the large bowel. A fatal termination ensued in the 5 cases in which *Bact. funduliformis* was cultivated from the blood. Multiple abscesses in the liver and lungs were observed at autopsy. Pyelophlebitis was found in 3 cases. The authors concluded that *Bact. funduliformis* septicemia should be suspected when postoperative convalescence is interrupted by a chill, fever, profuse sweating and jaundice. In Case 4 of the present series, *Bacteroides* were recovered in mixed culture from a liver abscess in a man dying of sepsis after colectomy. In Case 2, a *Bacteroides* septicemia arose from an abdominal abscess.

Following Infections of Genitourinary Tract

Bacteroides septicemias arising from the genitourinary tract have been observed in cases of septic abortion and of puerperal sepsis and in postoperative infections. *Bact. fragilis* was cultivated from the blood of 2 women with chills and fever following abortion.^{17, 22} Metastatic abscesses did not develop, and both women recovered within a week. *Bact. fragilis*, however, has been cultivated from the blood in a fatal case of post-partum septicemia with liver abscess.²³ Two fatal cases of *Bacteroides* septicemia following operations have been reported by Thompson and Beaver,²⁴ who²⁵ have since identified the strains from both cases as *Bact. funduliformis*. Both cases occurred in elderly men, one of whom had suprapubic drainage for carcinoma of the bladder, and the other of whom underwent prostatectomy and removal of stones from the bladder. Chills, fever and leukocytosis appeared ten to eighteen days postoperatively, and death occurred after five to six days of fever. Multiple abscesses were found in the lungs.

Following Infected Wounds

Bacteroides septicemias arising from wounds were observed by Bogdán²⁶ in Hungary during World War I in soldiers with gunshot wounds involving bones, that is, deep wounds in which conditions were favorable for the development of anaerobic infections. In some cases infection around the wound seemed slight, whereas in others it progressed to gangrene or thrombophlebitis. The onset of septicemia was marked by the appearance of chills and

fever in soldiers who had appeared to be making a satisfactory convalescence. There was severe pain over the region of the liver, with radiation to the right shoulder. Jaundice was frequently noted. The course of the disease was punctuated by the development of metastatic abscesses in the liver, lungs, spleen and joints. Of 24 patients, 16 died after illnesses of about two weeks. These *Bacteroides* wound infections appeared to spread from one patient to another, since all occurred in two nearby hospitals and appeared in rapid succession until the transmissibility of the disease was recognized and greater precautions were taken in treatment of the wounds.

Buday²⁷ demonstrated that the etiologic agent in a similar series of wounded soldiers with septicemias was a *Bacteroides*, which has since been known as *Bact. pyogenes anaerobius*. The presence of serum in the medium was necessary for growth. Buday's bacillus was closely similar to *Bact. funduliformis* and was placed by Weinberg et al.⁵ in that group.

CASE 1.* A 22-year-old man was admitted on June 6, 1939, with a complaint of chills, fever, headache and sore throat of 14 days' duration. He had previously been in good health. Several days after the onset of the illness, a tonsillar abscess had broken down spontaneously. On admission, the temperature was 105.6°F., the pulse 125, and the respirations 28. The patient appeared to be very ill. Both tonsils were hypertrophied and covered with a profuse, thick, white exudate. There were enlarged lymph nodes at the angles of the jaw. The remainder of the physical examination was not remarkable.

The patient was desperately ill throughout the hospital course and exhibited a septic temperature, with daily excursions between 101 and 106°F. The pulse ranged between 110 and 150. He was given sulfanilamide for 4 days, with a resulting blood level of 13.3 mg. per 100 cc., but the drug was discontinued because of the appearance of jaundice, which became steadily deeper. On the 5th day, fluctuation was observed over the right acromioclavicular joint. Incision and drainage of this joint yielded 60 cc. of thick, creamy-yellow pus containing innumerable gram-negative bacilli and 530,000 white cells per cubic millimeter, 95 per cent of which were polymorphonuclear leukocytes. The left arm became swollen and painful, and crepitus due to gas in the tissues was noted. An extensive abscess developed involving the entire left elbow and upper arm. This was incised and drained on June 19. The patient died on June 22, a month after the onset of his illness.

On admission, the white-cell count was 15,500, with 82 per cent neutrophils. The red-cell count was 4,600,000, and the hemoglobin 90 per cent. The urine gave a ++ test for albumin. Despite repeated transfusions, the red-cell count fell to 1,940,000. The serum bilirubin level (van den Bergh reaction) rose from 10.1 mg. per 100 cc. (biphasic) on June 9 to 31.8 mg. (direct) on June 20.

Bacteriology. Blood cultures and cultures of pus from the right acromioclavicular joint were made in meat tubes during life. Gram-negative bacilli were cultivated from both sources. Broth cultures exhibited diffuse turbidity, with production of gas and a foul odor. Colonies on ascitic agar plates were smooth, yellowish white and convex with an entire edge and attained a diameter of 1.0 to 1.5 mm. after 48 hours' incubation. Colonies on blood agar plates were nonhemolytic. The organisms were markedly pleomorphic in size and shape, producing long filaments and large, round bodies. They were strictly anaerobic. Neither spores, capsules nor motility was seen. A young pleuropneumonia-like growth (L-type variation) was observed beneath and near some of the bacterial colonies.¹¹ Owing to its marked pleomorphism, this strain has been placed in the *Bact. funduliformis* group.

*We are indebted to Dr. L. Dienes and Dr. E. R. Sullivan for permission to report this case.

CASE 2. A 26-year-old nurse delivered a normal baby (her first child) on September 30, 1941. The day after delivery she had a chill with a temperature of 105°F. There was spasm and tenderness in the left lower quadrant. On the following day, 250 cc. of foul, thin pus gushed from the rectum. Sulfadiazine was given for 4 weeks, with a dosage of 6 to 3 gm. a day. The temperature ranged between 101 and 103°F. for 1 week, after which it remained normal for 4 days. Following this, there was another chill and 4 more days of fever. The patient completely recovered and was discharged on November 1, 1941. The infection was believed to have originated from an abscess that ruptured into the bowel.

The white-cell count ranged between 13,250 and 11,800, with 88 per cent neutrophils. The red-cell count remained about 3,500,000, and the hemoglobin about 65 per cent. The urine was not remarkable. The blood level of sulfadiazine ranged from 4.6 to 10 mg. per 100 cc.

Bacteriology. One half to 1 cubic centimeter of blood taken on two occasions while the patient was having a chill was inoculated into four meat tubes. Growth was obtained on both occasions. Diffuse turbidity occurred, with the production of a small amount of gas, which did not have a particularly foul odor. Colonies on ascitic agar plates were smooth, grayish white and convex with an entire edge and attained a diameter of 1 mm. after 48 hours' incubation. Colonies on blood agar plates were nonhemolytic. The organisms were small gram-negative bacilli 1.5 to 2 microns in length and quite regular in size and shape. They did not produce large bodies, and L-type variation was not observed. They were strictly anaerobic. Neither spores, capsules nor motility was seen. Owing to its nonpleomorphic character, this strain was placed in the *Bact. fragilis* group.

Cases 1 and 2 bear out the impression gained from the literature of the greater severity of septicemias due to the pleomorphic *Bacteroides* (*Bact. funduliformis* group) than of those due to *Bacteroides* of uniform morphology (*Bact. fragilis* group). Sulfanilamide did not appear of value in Case 1 during the four days it was given. The prompt recovery in Case 2 was probably due to spontaneous perforation and drainage of the abdominal abscess. It is impossible to determine whether sulfadiazine was of value, since comparable recoveries in previously cited cases of septicemia due to nonpleomorphic *Bacteroides* occurred without drug treatment.

The jaundice that led to the discontinuance of the drug in Case 1 may well have been a result of the infection. In fact, jaundice is so frequently seen in *Bact. funduliformis* septicemias that its occurrence should be regarded as evidence in favor of liver abscess rather than drug intoxication, especially when other signs of drug intoxication are lacking.

Gas in the tissues, as noted in Case 1 and in a previously cited case¹⁶ is occasionally a point of value in differential diagnosis. All the strains encountered in this study produce gas in cultures.

The treatment of *Bacteroides* septicemias corresponds to that of other septicemias arising from focal infections and producing metastases. Appropriate surgical procedures, such as drainage of pus and ligation and excision of affected veins, are the important factors. A case has already been cited of recovery following drainage of metastatic joint abscesses and another following sequestrectomy of an infected bone. Rib resection and drainage was followed by recovery of 2 out of 3 patients with *Bact. funduliformis* empyema occurring after upper

respiratory infection.²⁵ Buday²⁷ noted that the only recoveries in his group of soldiers occurred when liver abscesses perforated the lung and drained through the bronchi. There is a recent report of recovery from postanginal *Bact. funduliformis* septicemia following excision of the internal jugular vein on the side of the affected tonsil.²⁹ None of these patients received sulfonamides.

Sulfonamides have been used in 2 reported cases. A patient with *Bact. funduliformis* liver abscess recovered following sulfathiazole therapy and surgical drainage.³⁰ Another with postanginal *Bact. funduliformis* septicemia was treated with sulfapyridine and recovered.¹⁵ This drug was said to have affected the course favorably, but the major factor was apparently rib resection with drainage of an empyema. There is therefore no adequate clinical evidence that sulfonamides are of value. Animal experiments, however, indicate that sulfanilamide inhibits the spread of abscesses produced by subcutaneous injections of *Bacteroides* cultures³¹ and effectively controls septicemias produced by intravenous injections.³²

BACTEROIDES MENINGITIS

Between 1898 and 1939, at least 11 cases of *Bacteroides* meningitis were reported. Brain abscesses were present in 4 of these. All the cases were fatal, and all arose from chronic otitis media except one of brain abscess that occurred in a patient with bronchiectasis. Between 1940 and 1943, 5 cases of *Bacteroides* meningitis have been seen at the Massachusetts Eye and Ear Infirmary. All arose from chronic otitis media that had extended into the mastoid or labyrinth. Brain abscess occurred in 2 cases.

The onset of *Bacteroides* meningitis is acute, and the symptoms and course are similar to those of meningitides caused by other pyogenic organisms. In smears of spinal fluid, the organisms may be seen as small gram-negative bacilli lying within the cells or extracellularly. They may be mistaken for influenza bacilli. Diagnosis depends on cultivation of the organisms, and meat tubes enriched with ascitic fluid have proved highly satisfactory for this purpose. In one patient, organisms could not be found in direct smears of the spinal fluid but were recovered in cultures. Such a case might have been regarded as so-called "sterile meningitis" if anaerobic cultures had not been repeatedly made. Cultures should be held at least two weeks before being discarded as sterile.

In view of the uniformly fatal outcome of all previously known cases, it was of considerable interest that 4 of the 5 patients in this series recovered. Early and adequate surgical drainage, repeated lumbar punctures and the use of intravenous fluids and transfusions appeared to be the major factors in aiding recovery, but there was evidence that sulfadiazine was a useful adjunct in a patient who had

three separate episodes of meningitis, each of which subsided promptly on administration of the drug. Detailed reports of these cases have already been published.^{33, 34}

BACTEROIDES PERITONITIS

Bacteroides are among the most frequent organisms in human feces, being present in 90 per cent of stools,³ often in greater numbers than the colon bacillus.³⁵ It is therefore to be expected that *Bacteroides* will be present in the peritoneum when leakage from the bowel has occurred. In the classic studies of Veillon and Zuber,³⁶ various species of *Bacteroides* were recovered from the peritoneum in a score of cases of gangrenous appendicitis, and these authors concluded that *Bacteroides* were the most frequent organisms in this condition.

There are many subsequent accounts of strains isolated from the peritoneum.⁵ Most strains were recovered at autopsy, but it should not be inferred that the cultivation of *Bacteroides* from the peritoneum necessarily confers an unfavorable prognosis. We have cultivated them during life from 5 patients, only 1 of whom died. Among 3 patients with gangrenous appendicitis yielding *Bacteroides*, 2 recovered uneventfully. Case 5 is cited as an example. The third (Case 3) developed a subdiaphragmatic abscess that yielded a pure culture of *Bacteroides*. As described in the section on septicemia, thrombophlebitis and invasion of the blood stream by *Bacteroides* with formation of liver and lung abscesses may arise from abdominal infections. In Case 4, the patient died, having developed an abdominal abscess and a liver abscess following colectomy.

Peritonitis resulting from leakage from the bowel is of course a mixed infection. It was therefore of interest to encounter a case of peritonitis from which *Bacteroides* were isolated in pure culture. In this patient (Case 6), the peritonitis arose from a salpingitis and, although extensive, subsided within a few days. Clinically, it simulated gonococcal peritonitis.

CASE 3. A 53-year-old laborer was admitted on June 27, 1941, with a ruptured appendix and peritonitis. Following operation, he remained in the hospital for 8 months with a pelvic abscess that continued to drain pus through a fecal fistula. Jaundice appeared in November but gradually cleared. In December, a subdiaphragmatic abscess developed on the left and was drained surgically. Treatment included sulfadiazine and sulfathiazole, as well as transfusions. The patient improved slowly and was discharged to a nursing home in March, 1942.

The white-cell count ranged from 5400 to 13,400, and the red-cell count from 2,900,000 to 4,700,000. The serum bilirubin level (van den Bergh reaction) in November was 14.6 mg. per 100 cc. (biphasic).

Bacteriology. Pus from the ruptured appendix and fecal fistula yielded *Bacteroides*, *Escherichia coli*, alpha-hemolytic and nonhemolytic streptococci, *Staphylococcus aureus* and several species of *Clostridia*—the flora of the colon. Abdominal fluid withdrawn in November because of ascites yielded many colonies of *Bacteroides* and anaerobic diphtheroids and a few colonies of alpha-hemolytic streptococci. This fluid was not purulent. Pus from the subdiaphragmatic abscess yielded a pure culture of *Bacteroides*. The Bac-

teroides from this case possessed morphologic and cultural characteristics similar to those of the strain from Case 2 and were regarded as *Bact. fragilis*.

CASE 4. A 63-year-old factory worker had an ileotransverse colostomy on April 27, 1941. A right colectomy for removal of carcinoma of the ascending colon was done 11 days later. A right-gutter abscess and fecal fistula developed. The temperature, which had ranged between 100 and 102°F., suddenly began to spike to 103 and 105°, and tenderness was noted over the anterior right costal margin. Sulfapyridine therapy (6 gm. a day) was instituted, but the patient died 1 week after the onset of the spiking fever — 23 days after the colectomy.

Autopsy. In the right flank there was a large abscess cavity into which fecal material was leaking from the blind end of the transverse colon. The right lobe of the liver contained a multiloculated, necrotic abscess filled with greenish-yellow pus of foul odor. No evidence of thrombosis was found in the portal circulation. There was an area of bronchopneumonia in the right lower lobe.

Bacteriology. A blood culture taken during life grew alpha-hemolytic streptococci. Pus from the abscess yielded *Esch. coli*, *Staph. aureus* and nonhemolytic streptococci. Anaerobic cultures were not made. Culture of the heart's blood at autopsy yielded diptheroids that were regarded as contaminants. Pus from the liver abscess yielded an abundant growth of *Bact. fragilis* in mixed culture with *Proteus vulgaris* and nonhemolytic streptococci.

CASE 5. A 37-year-old chauffeur was admitted on May 31, 1941, with abdominal pain of 4 days' duration. At operation a necrotic appendix was found in the center of a large abscess cavity. Sulfanilamide was placed in this cavity, and cigarette drains were inserted. Sulfapyridine (6 gm. a day) was given for 5 days. The patient improved steadily and was discharged well after a stay of 1 month in the hospital. A fecal fistula healed solidly 1 month after discharge.

Bacteriology. Pus taken at operation from the appendiceal abscess yielded an abundant growth of *Bact. fragilis*, *Esch. coli* and a few colonies of alpha-hemolytic streptococci.

CASE 6.* A 50-year-old, unmarried woman was admitted on December 21, 1940, because of lower abdominal pain of 18 hours' duration. There was boardlike rigidity in both lower quadrants of the abdomen. The temperature was 100.5°F., and the pulse 90. Sulfathiazole (1 gm. every 4 hours) was given for 6 days. The temperature fell to normal within 3 days, the pulse remaining around 90. X-ray examination showed many dilated loops of small bowel, suggesting obstruction, and exploratory laparotomy was performed 3 days after admission. The bowel was diffusely coated with creamy-yellow pus, and a large amount of pus was found in the pelvis. There was no perforation or obstruction of the bowel. The right tube appeared normal. There was hydrosalpinx on the left. The abdomen was closed without drainage. The patient appeared quite well after 1 week.

Total hysterectomy, bilateral salpingectomy and right oophorectomy were done 2 weeks later. The right tube was filled with milky fluid and purulent exudate. The right ovary contained many cysts filled with milky fluid. The patient made an uneventful recovery and was discharged well on February 9.

The gonococcus complement-fixation test was negative. The white-cell count fell from 28,700 on admission to 9300 several days later, with a corresponding fall in neutrophils from 92 to 61 per cent. The red-cell count rose from 3,860,000 to 4,870,000. The urine gave a + test for albumin but was otherwise negative.

Bacteriology. Cervical cultures were negative for gonococci but yielded an abundant growth of aerobic pleuropneumonia-like organisms. Aerobic cultures of pus obtained from the peritoneum at the first operation remained sterile, but on anaerobic horse-serum-agar plates and semisolid rabbit-serum agar *Bact. funduliformis* was isolated. On anaerobic plates a few pleuropneumonia-like colonies also developed. Subcultures of this strain of *Bacteroides* showed that it produced anaerobic pleuropneumonia-like (L) colonies as variant growth forms. The organisms may have been present in the tissues in the L form, since direct smears of the pus revealed no ordinary bacilli, but the polymorphonuclear

leukocytes were distended by masses of small granules. Photographs and studies of this bacillus and its relation to the L forms have been published elsewhere.¹¹

As stated above, the cultivation of *Bacteroides* from the peritoneum may be expected in cases in which there has been leakage from the bowel and should not necessarily confer an unfavorable prognosis. The participation of these organisms in intra-abdominal infections should be borne in mind, however, and anaerobic blood cultures should be made in cases of peritonitis exhibiting septic fever or jaundice.

LOCALIZED BACTEROIDES INFECTIONS

Like other natural inhabitants of mucous membranes, the *Bacteroides* may give rise to or participate in localized infections in or near these sites, being found either in pure culture or together with other organisms. As described in preceding sections, generalized *Bacteroides* infections may arise from such localized processes.

An extensive but neglected study on the bacteriology of otitis media was made in 1900 by Rist,³⁷ who concluded that the *Bacteroides* played an important role in chronic suppurative otitis media, particularly in cases with foul-smelling discharge, whereas ordinary pyogenic cocci were the most important agents in acute otitis. We have cultivated *Bacteroides* from 2 patients with chronic suppurative otitis media.

Bacteroides have been recovered from various urinary infections in males and females, from cervicitis and Bartholin abscesses^{4, 38} and from the lochia of women with post-partum fever.³⁹ We found them in mixed culture in 3 women with chronic endocervicitis and in 2 men with chronic prostatitis. *Bact. funduliformis* was recovered in pure culture from the pus of a kidney abscess (Case 7). A discussion of the distribution of these organisms in the healthy female genital tract and in genitourinary infections is given at the end of Rist's paper.

Bacteroides have been cultivated from lung abscesses.⁴⁰ Dack⁶ believes that they may be of importance in chronic ulcerative colitis, either as primary agents or as secondary invaders. They have been found in abscesses on the hands of persons who had scratched the skin while working with material from animals infected with *Actinomyces necrophorus* (presumably *Bact. funduliformis*).^{5, 6} Such abscesses are usually small and self-limited. We repeatedly recovered *Bact. funduliformis* in mixed culture with staphylococci or streptococci from a severe case of suppurative hydroadenitis of nineteen years' duration. At the time this patient was seen, multiple draining sinus tracts were present on the buttocks and many healed scars were seen on the face, in the axillas and over the chest and back.

*We are indebted to Dr. L. Dienes and Dr. J. V. Meigs for permission to report this case.

Bact. fragilis was isolated in this laboratory from the eye and cervix of a patient with conjunctivitis and arthritis who was regarded as possibly suffering from Reiter's disease. These organisms were recovered from the eye in pure culture, but could not be isolated from samples of blood or fluid from an affected joint or from other cases of Reiter's disease. Gonococci were not demonstrable. Until the cause of this disease is known, the etiologic significance of *Bacteroides* cannot be established.

CASE 7. An 83-year-old man was admitted on August 7, 1942, with a complaint of aching pain in the left flank of 3 weeks' duration. A large, fluctuant mass was felt in the left upper quadrant of the abdomen. X-ray examination revealed renal calculi on the left. The temperature was 100°F., and the white-cell count 16,000. The urine contained large numbers of red and white cells. A large perinephric abscess was found at operation. About 1000 cc. of foul yellow pus was drained from the abscess, and the kidney was removed. The abscess had eroded into the wall of the splenic flexure of the large bowel but had not penetrated the mucosa. Following the operation, sulfadiazine (2 gm. a day) was given for 10 days. A fecal fistula developed, but the patient did well and ran an essentially afebrile course. He was discharged 2 months after admission. The fistula closed within 5 months.

Bacteriology. Pus from the kidney abscess inoculated into meat tubes yielded a pure culture of *Bact. funduliformis*. The organisms were extremely pleomorphic, forming filaments and large bodies and exhibiting L-type variation. This strain, designated as No. 132, has been extensively studied.^{8,11}

BACTERIOLOGIC OBSERVATIONS

A great many species names have been given to the numerous strains of *Bacteroides* isolated in the last fifty years. The classification proposed by Weinberg et al.⁶ affords an instructive outline of the situation. The more recent classification of Prévot⁴¹ appears to possess certain fundamental merit in its broader aspects, but much more study is needed before any conclusion can be reached concerning which strains are true species and which are merely varieties.

Substantial progress has been made in Rettger's laboratory, where seventy-three strains of *Bacteroides* were found to fall into four serologic groups.³⁵ Later, two groups were recognized, chiefly on the basis of whether the strains were pleomorphic or nonpleomorphic.⁴² Henthorne, Thompson and Beaver²⁵ found that six pleomorphic strains fell into one serologic group, whereas three nonpleomorphic strains fell into another. We have adopted the convention of placing pleomorphic strains in a *Bact. funduliformis* group and nonpleomorphic strains in a *Bact. fragilis* group. The latter corresponds to the *Bact. vulgatus* group of Lewis and Rettger.⁴² The name "*fragilis*" is preferred because of its general use in the literature dealing with strains from infectious processes. This simple separation into two groups is obviously a temporary expedient, but it seems to have some clinical merit, since the septicemias due to pleomorphic strains appear to be severer than those due to nonpleomorphic strains.

Following is a résumé of data on strains recovered in this laboratory.

Meat tubes sealed with paraffin and Brewer's thioglycollate broth⁴³ proved to be satisfactory liquid mediums. For primary isolation, these mediums are enriched with 30 per cent aseptic fluid, to obtain growth within twenty-four to forty-eight hours. In an unenriched medium, growth may not appear until after a week or more.

Both pleomorphic and nonpleomorphic strains grow diffusely, with occasional exceptions in each group. Pleomorphic strains produce large, round bodies in abundance and often chains and filaments. Gas production is vigorous, and the cultures have a foul smell. Nonpleomorphic strains grow as uniform, small bacilli, produce less gas and have a less marked odor.

Anaerobiosis for plate cultures was obtained by the Fortner method.⁴⁴ After forty-eight hours' incubation, colonies on aseptic agar plates average 1 mm. in diameter. On blood-agar plates they are smaller. The colonies are smooth, white or gray, convex with an entire edge and nonhemolytic. Some pleomorphic strains produce yellow colonies and may exhibit beta hemolysis inconstantly. Of seven pleomorphic strains, three produced pleuropneumonia-like colonies as variant growth forms (L-type variation). Both L-type colonies and regular bacilli were seen to develop from the large bodies, which are so frequent in these strains and which were shown to contain a nuclear apparatus.^{9,12}

Of three pleomorphic strains tested, all produced hydrogen sulfide and one produced indol. Of four nonpleomorphic strains tested, two produced small amounts of hydrogen sulfide and none produced indol. Heat-resistance tests made with three pleomorphic and two nonpleomorphic strains showed that the organisms did not survive a temperature of 60°C. for twenty minutes. A nonpleomorphic strain from a case of meningitis produced large capsules. Motile organisms were never seen, nor were spores. The large bodies cannot be regarded as spores, since they are not heat-resistant and do not have the highly refractile quality characteristic of spores. All strains were gram-negative and strictly anaerobic.

Cultures of three pleomorphic strains injected subcutaneously into guinea pigs and rabbits produced only local abscesses. Intravenous injection of rabbits occasionally resulted in death with multiple abscesses or accompanied by cachexia with no localized lesions. Mice two weeks old injected intraperitoneally with one strain died within forty-eight hours with diffuse peritonitis. Old mice were not susceptible.

DISCUSSION

Bacteroides are natural inhabitants of mucous membranes, from which sites they may invade the tissues, blood or body cavities. They give rise to, or participate in, a great variety of pathologic processes. That *Bacteroides* infections are by no means rare is attested by the observation of 20 cases in this hospital within four years. The types of infection can be classified as follows: septicemia arising from throat infections, otitis media, surgery or infections of the large bowel, surgery or infections of the genitourinary tract or gunshot wounds; meningitis arising from chronic otitis media; peritonitis arising from appendicitis or leakage from colon (a mixed infection) or from salpingitis; infections of mucous membranes, including tonsillitis, otitis media, chronic cervicitis, and chronic prostatitis; and abscesses of the tonsils, liver, lungs, joints, brain, kidneys, Bartholin's glands, periurethral glands and skin.

The most frequent severe *Bacteroides* infections are septicemias arising from throat infections or following operations on the large bowel and meningitides arising from chronic otitis media. A case of *Bacteroides* peritonitis arising from salpingitis

and clinically simulating gonococcal peritonitis is noteworthy. The occurrence of *Bacteroides septiciemias* in epidemic form in a group of soldiers with gunshot wounds, as described by Bogdán,²⁶ is of unusual interest. Although most *Bacteroides* infections appear to arise from organisms that are part of the normal body flora, this epidemic suggests that in some cases implantation of particularly virulent strains is a factor, and indicates the desirability of isolating recognized cases occurring in hospitals containing wounded men.

It is curious that *Bacteroides* and infections produced by them are not mentioned in some outstanding clinical and bacteriologic textbooks. This neglect is probably due to the fact that these organisms are easily missed in routine bacteriologic study, since they are anaerobic, tend to grow slowly and often require the presence of serum or ascitic fluid in the medium. It is hoped that this paper will stimulate more careful search for these organisms.

SUMMARY

A review of *Bacteroides* infections based on cases collected from the literature and on those seen at the Massachusetts General Hospital is presented. The types of infections in which *Bacteroides* should be suspected are described. Methods for the cultivation and classification of the organisms are discussed.

Treatment consists chiefly of surgical and supportive measures. Animal experiments indicate that sulfonamides may be of value, but there is as yet no conclusive clinical evidence to this effect.

ALKALOSIS DURING SULFADIAZINE THERAPY FOR PNEUMOCOCCAL MENINGITIS*

Report of a Case

FRANK GIUNTA, M.D.,† AND RUSSEL O. BOWMAN, Ph.D.‡

PROVIDENCE, RHODE ISLAND

MENINGITIS due to a pneumococcus has a high mortality.¹ When complicated by diabetes and poor kidney function, it becomes a problem in therapy, as illustrated by the following case.

A 61-year-old, Italian housewife entered the Rhode Island Hospital on March 13, 1944, in a comatose state with a 4-day history of headache, backache, epigastric pain and vomiting. She had become drowsy 12 hours before admission and had gradually lapsed into coma.

Physical examination revealed a comatose woman breathing noisily and heavily through the mouth. The skin was clear. The eyes deviated to the left. The pupils were equal. The ears were normal. The neck was rigid. The lungs, heart and abdomen were not remarkable. The blood pressure was 180/90. The temperature by mouth was 104.2°F. The extremities showed no edema or varicosities. Bilateral Kernig signs were elicited. The patella and biceps reflexes were normal.

On admission the patient was suspected of having meningitis. A lumbar puncture yielded cloudy fluid under 370 mm. of pressure containing Type 3 pneumococci. The blood-sugar level was 680 mg. per 100 cc. and the carbon dioxide combining power 33 vols. per cent. The blood urea nitrogen was 26 mg. per 100 cc., and the creatinine 3.2 mg. The blood culture developed Type 3 pneumococcus. A blood Hinton reaction was positive. The urine showed a +++ test for sugar, a ++ test for albumin, a specific gravity of 1.022 and a positive test for acetone. The sediment contained many red and white cells and numerous granular casts. The white-cell count was 27,800, with 93 per cent polymorphonuclear leukocytes and 7 per cent lymphocytes. The red-cell count was 3,900,000, and the hemoglobin 13.1 gm.

Within the first 2 hours of admission, the patient was started on 5 gm. of sulfadiazine intravenously and was given 100,000 units of Type 3 antipneumococcus serum by the same route (Fig. 1). She was given 50 units of regular insulin and 50 units of protamine-zinc insulin subcutaneously and also 50 units of regular insulin in normal saline solution parenterally. Twelve hours later, she was started on a pre-coma regime consisting of 5 units of regular insulin for each "+" of sugar in the urine. She received 2 gm. of sulfadiazine intravenously every 8 hours. The total parenteral fluid therapy during the first day totaled 2000 cc. of normal saline solution and 2000 cc. of 5 per cent dextrose solution. The patient was still in coma the following day. The urinary output was extremely low. The sediment continued to show many red and white cells and a ++ test for albumin. The blood-sugar level had dropped to 362 mg. per 100 cc. Fifty thousand more units of antiserum was given.

On the 3rd hospital day, the patient responded to treatment and began to take sodium bicarbonate (1 heaping teaspoonful in water every 2 hours, alternating with and without sulfadiazine). The blood culture was sterile. X-ray films of the chest showed no abnormalities. The blood urea nitrogen had risen to 41 mg. per 100 cc., and the creatinine to 3.3 mg. The blood-sulfadiazine level was 18.8 mg. per 100 cc. of free drug and 22.6 mg. of total drug. The urinary sediment still contained numerous red and white cells and albumin.

On the 4th day, the blood urea nitrogen was 54 mg. per 100 cc., and the blood-sulfadiazine level 20.2 mg. of free and 28.6 mg. of total drug. On the 5th day, the temperature was almost normal, and the patient was subjectively and objectively much better. The blood urea nitrogen was 56 mg. per 100 cc., the creatinine 5 mg., and the sugar 414 mg.

Sodium bicarbonate was continued as previously noted. On the 6th day, diarrhea and distention were noted. Sodium bicarbonate was given only once every 4 hours. Kaopectate and paregoric were administered. On the 7th day, the patient was well enough to take a liquid diet. She was still receiving parenteral fluids. On the following day, however, she became less responsive and had a convulsive seizure. The eyes deviated to the left, and there was spasm of the right side of the face and spasticity of the entire body. After the seizure, twitching of various muscles of the body was noted, particularly those of the face and upper extremities.

From the 3rd to the 8th day, the patient received 345 gm. of sodium bicarbonate by mouth. The total fluid intake by all routes in this period amounted to 17,600 cc., and the total urinary output was 5020 cc.

On the 8th day, the carbon dioxide combining power was 110 vols. per cent, compared with 33 vols. 7 days previously. The whole-blood chloride level, expressed as sodium chloride, was 292 mg. per 100 cc., and the blood-sulfadiazine level 14.2 mg. of free and 25.1 mg. of total drug. The Chvostek sign was markedly positive, and the patient was having periods of apnea, followed by rapid breathing. She was stuporous, but responded to vigorous shaking and took fluids by mouth. She was given calcium chloride by vein and ammonium chloride by mouth. The convulsive seizures stopped, but the twitching of various muscles continued. An attempt was made to increase the chlorides by intravenous normal saline solution, since the patient had improved only slightly after 24 hours' treatment with 18.5 gm. of ammonium chloride and 3 gm. of calcium chloride. Breathing of 10 per cent carbon dioxide and 90 per cent oxygen was attempted to relieve the apneic phases, but this had only a temporary effect. Ten cubic centimeters of 0.07 per cent hydrochloric acid and 5 cc. of 0.5 per cent hydrochloric acid were administered intravenously, but no more was given for fear of further damaging the kidneys by formation of acid hematin. The patient was becoming edematous. Abdominal distention due to gas was marked.

In one day the carbon dioxide combining power was brought down to only 104 vols. per cent. The sodium chloride had risen to 330 mg., the blood urea nitrogen was 50 mg. per 100 cc., and the creatinine 5.1 mg.

On the 10th day, after one more day of treatment of the alkalosis with 2 gm. of calcium chloride intravenously and 6 gm. of ammonium chloride by mouth, the carbon dioxide combining power was down to 86 vols. per cent and the sodium chloride up to 378 mg.¹ The blood urea nitrogen was 50 mg., and the creatinine 6 mg. per 100 cc. The patient looked much better, but the urinary output was decreasing.

On the 11th day, because the kidney output was only 400 cc., ureteral catheterization was done. Sulfadiazine was stopped because the patient had run a near-normal temperature for several days and because it was suspected that kidney shutdown might have been due to the drug. Insulin was also stopped, because with the decrease in infection the severity of the diabetes decreased. The blood urea nitrogen had risen to 62 mg. and the creatinine to 6.5 mg.; the carbon dioxide combining power had dropped to 75 vols. per cent, and the sodium chloride to 332 mg.

On the 12th day, the kidney output was less than 100 cc. Tissue edema was marked. The urine was small in amount and was grossly bloody and full of sediment.

On the 15th day, after persistent continued treatment with intravenous solutions, the kidneys were excreting large amounts of urine. Because the total protein was 3.7 gm. per 100 cc., 500 cc. of blood plasma was given in an attempt to relieve the edema. The creatinine was 8.8 mg., the blood urea nitrogen 96 mg., and the sodium chloride 340 mg. per 100 cc. On the 17th day, the urinary output continued high. Edema had decreased considerably. The patient felt well and was put on a liquid diet. A lumbar puncture yielded spinal fluid with an initial pressure of 350 mm., a protein of

*From the Medical Service and the Laboratory of the Rhode Island Hospital.

†Formerly, intern, Rhode Island Hospital.

‡Research biochemist, Rhode Island Hospital, and associate professor of biochemistry, Rhode Island College of Pharmacy.

28 mg. per 100 cc. and 1 polymorphonuclear and 10 lymphocytic cells per cubic millimeter. The blood urea nitrogen and creatinine levels were dropping, and the carbon dioxide combining power was 62 vols. per cent. Two days later the patient became comatose. No cause was found, although

The patient was started on penicillin, being given 15,000 units intramuscularly every 3 hours. The response both clinically and subjectively was excellent. The temperature dropped to normal. In 3 days she received 195,000 Oxford units of penicillin, and recovery from the pneumonia and

FIGURE 1.

cerebral thrombosis was suspected. She came out of coma without treatment in 6 hours.

On the 24th day, the patient developed a temperature of 103.5°F. Lobar pneumonia was diagnosed clinically. X-ray examination showed consolidation in the chest. A lumbar puncture yielded clear spinal fluid with 95 mg. of protein per 100 cc., 45 polymorphonuclear cells and 25 lymphocytes per cubic millimeter, a positive Hinton reaction and a gold-sol curve of 5554321000.

On the 26th day, blood and urine cultures were reported as positive for a coagulase-positive *Staphylococcus aureus*. The blood urea nitrogen was 48 mg., the creatinine 3.3 mg., and the blood sugar 268 mg. The white-cell count was

septicemia appeared probable when the patient suddenly had a convulsive seizure lasting 5 minutes and died.

Permission for autopsy was refused.

DISCUSSION

On admission, the carbon dioxide combining power of 33 vols. per cent and a positive test for acetone in the urine indicated that diabetes mellitus was a contributing, but not the major, factor in producing unconsciousness. The need for insulin, in

this previously unknown diabetic patient, decreased as the infection was controlled. She had poor kidney function, as shown by the urine sediment and albumin, a specific gravity of 1.022 in the presence of both albumin and sugar, and nitrogen retention that increased after adequate hydration. The dosage of sulfadiazine was not high, but excretion was poor. This is shown by the high values for free drug and by an amount of acetylated drug in the blood about ten times the usual one.

Sodium bicarbonate was given by mouth to aid in excretion of the sulfadiazine. In pneumonia patients we have given up to 60 gm. a day, but still find in some cases a urine with a pH less than 7. This patient was given 345 gm. in a period of five days, with the resulting coma and convulsions of alkalosis. The kidney insufficiency undoubtedly contributed to the alkalosis by failure of acid-base regulation. In subjects with normal kidneys, Thompson, Mitchell and Kolb² were able to give daily doses of 60, 75 and 130 gm. of sodium bicarbonate in a three-day period, respectively, without the development of alkalosis and with a rise in the carbon dioxide combining power only to 68 vols. per cent. Jeghers and Lerner³ believe that 8 per cent of cases of peptic ulcer treated with alkalis containing sodium bicarbonate develop alkalosis, although the syndrome is seldom recognized.

The reaction of the urine on the second and third hospital days was pH 5.0. On the fourth and fifth days it was pH 8.0, and on the ninth day, after one day of acid therapy, it was pH 7.0. Usually an alkaline urine is excreted when the carbon dioxide combining power is 75 vols. per cent or more.

Other signs accompanying the development of alkalosis were edema, coma, apnea, a positive Chvostek sign and convulsions. Excess alkali causes the tissue proteins to hold more water and the interstitial fluid increases, especially when a low plasma protein is present. Coma with apnea alternating with hyperpnea is found in severe alkalosis. During the compensated phase, carbon dioxide accumulates as carbonic acid in the plasma, but when the sodium bicarbonate (carbon dioxide combining power) rises higher, the pH of the plasma shifts to higher values and coma begins. The relative alkalinity inhibits the response of the respiratory center to carbon dioxide, and periods of apnea followed by deep respiration may result. It also decreases the ionization of calcium compounds in the plasma, although there is no decrease in total calcium. With less than normal calcium ions neuromuscular irritability is increased, so that the Chvostek sign is positive, and with marked changes, convulsions may begin.

Calcium chloride is useful for emergency treatment, since for an hour or two it supplies extra calcium ions, and it also has a slight acidification action. Ammonium chloride is a better agent, since the cation is converted to urea by the liver and

some bicarbonate is replaced by chloride. The giving of intravenous hydrochloric acid is a rather direct attack on the alkalosis, since its reaction with bicarbonate forms carbon dioxide, which is excreted by the lungs, and sodium chloride. Treatment with intravenous sodium chloride solution depends on the ability of the kidney to excrete sodium bicarbonate and retain sodium chloride.

Treatment of this case with all these agents improved the alkalosis, as shown by a fall in carbon dioxide combining power, and with this there was a rise in the sodium chloride level of the blood. It was impossible to show a return to normal of blood chloride, probably because of rapid diffusion of the parenteral sodium chloride into the tissues and because of nitrogen retention, which, by phosphate and sulfate retention, left less blood base to exist as chloride. The blood sodium chloride of 292 mg. per 100 cc., found when the patient was in alkalosis, developed in spite of the giving of 9000 cc. of 0.85 sodium chloride solution during the previous seven days.

Sulfadiazine was continued for three days after the alkalosis episode. After it was stopped on the eleventh day because of a fall in urinary output, the nitrogen constituents of the blood rose for four days. The small amounts of urine voided contained blood and a crystalline sediment. Apparently the sodium chloride used to treat the alkalosis had caused a migration of fluids into tissue spaces, and sulfadiazine crystals in the kidney tubules had produced almost complete anuria. The kidneys recommenced excretion after the use of intravenous 5 and 10 per cent dextrose solutions in distilled water, and with increased urine output, the blood urea nitrogen and creatinine levels rose.

This patient had been comatose on four occasions while in the hospital. Coma on admission was most likely due to the meningitis together with diabetes. Coma on the eighth day was probably caused by alkalosis. There were two unexplained comas, one on the twentieth day and the other just preceding the convulsions and death. Although the positive blood and spinal-fluid Hinton reaction, a paretic colloidal-gold curve and increased total protein and cell count of the spinal fluid were consistent with neurosyphilis, this diagnosis was relegated to the background owing to the severer and more obvious infections present during the illness. It is unlikely that meningovascular syphilis was a contributing factor in this patient's death. Localized abscesses are found complicating pneumococcal meningitis. That this was the cause of death is not so likely. There were no progressive symptoms indicating increase in intracranial pressure, nor was the initial pressure on the last tap elevated. Other possible causes of death are a cerebral hemorrhage on a hypertensive basis, acute staphylococcal endocarditis with ruptured aortic cusp and resulting lodgment of an embolus in the cerebral artery, and an acute myocardial failure from the severe

and long illness. The last seems the most probable cause.

CONCLUSIONS

The administration of sulfadiazine and specific antipneumococcus serum helps to sterilize the blood stream and spinal fluid in cases of Type 3 infection.

A damaged kidney not only excretes sulfadiazine poorly but may cause alkalosis if sodium bicarbonate is given in considerable dosage with the sulfonamide. Careful observations of the blood urea nitrogen and blood-sulfonamide levels, the carbon dioxide combining power and the fluid balance are necessary in cases in which kidney function is abnormal.

Treatment of an alkalosis may cause renal shut-down when large amounts of sulfadiazine are present in the body.

Apparent sterilization of blood and spinal fluid from Type 3 pneumococci with specific antipneumococcus serum and sulfadiazine, apparent recovery from alkalosis and apparent sterilization of blood from *Staph. aureus* with penicillin were insufficient to save this patient's life.

CLINICAL NOTE

CUTANEOUS HORN

S. GEORGE BROWN, M.D.*

CONCORD, NEW HAMPSHIRE

PATIENTS with pronounced cutaneous horns are so rarely seen that the following case appears worthy of recording.

*Senior physician, Medical Service, New Hampshire State Hospital.

An 88-year-old man was admitted to the New Hampshire State Hospital with a horny growth on the back of the right hand (Fig. 1). It was about 15 cm. long, curving distally in a semicircle from the area of origin over the first and second metacarpophalangeal joints to the middle phalanx of the ring finger. It was apparently a hyperkeratosis. A relative stated that the growth started as a wart 10 years previously, and that the patient used to trim it with a razor blade. Gradually the tissue became hard and he filed or ground it down.

The growth was removed in toto and sent to the pathologist. According to the report, the specimen consisted of a

FIGURE 1.

horn 14.5 cm. long in the shape of the letter C. The diameter at the base was 4 cm., and that at the tip, which was blunt, was 1.5 cm. The horn was longitudinally striated. The color varied from light brown at the proximal end to dark brown at the tip. Microscopic examination of the tissue at the base revealed stratified squamous epithelium with long papillary processes, overlying fibrous connective tissue in which there were many lymphocytes. The stratum corneum was composed of innumerable layers. There was no evidence of malignant degeneration. The diagnosis was cutaneous horn.

The patient made an uneventful recovery from a skin graft, and is still in the hospital.

MEDICAL PROGRESS

DISEASES OF THE NEWBORN*

STEWART H. CLIFFORD, M.D.†

BROOKLINE, MASSACHUSETTS

THE relatively high death rates that still prevail during early infancy are the cause of much concern throughout the country. The infant mortality during the first year of life for the United States in 1941 was 45.3 deaths per 1000 live births.¹ Of these deaths 27.7, or 61 per cent, took place in the first month of life, while 18.1 or 29 per cent occurred in the first twenty-four hours of life.^{2,3}

The federal government, through the Children's Bureau, has taken a leading role in attempts to lower the incidence of such deaths. The Children's Bureau has encouraged state health departments to develop plans to improve the care of premature infants, and at least forty-three states have presented such a program.⁴ The Bureau, with the co-operation of various nationally recognized pediatric organizations, has prepared and published *Standards for the Care of Newborn Infants*. This authoritative pamphlet can be obtained by writing the Children's Bureau and should be studied by every hospital attempting the care of such infants. The Children's Bureau has also developed and published a booklet entitled *Plans for Hospital Nurseries*, which was drawn up with a view to protect the infants from infection and to facilitate the work of physicians and nurses.⁴ In addition, as a wartime measure, the Bureau has been given the responsibility of administering the Emergency Maternal and Infant Care (EMIC) Program for the wives and infants of enlisted men.

PREMATURITY

The ideal method of decreasing the number of deaths from prematurity would be to prevent the premature onset of labor; up to the present time, however, no one has succeeded in doing this except in a few isolated cases. It is therefore necessary to improve the environment into which the premature infant is born if its chances of survival are to be increased.⁵

Although a premature infant may suffer and die from any of the pathologic conditions affecting an infant born at term, there are many who fail to show pathologic lesions that can be discovered by known chemical or histologic means. The immediate reason why the majority of otherwise normal premature infants die is inability to absorb oxygen through the inadequately developed lung. As the fetus grows, capillaries gradually branch out from

the septal vessels and push their way between the cuboidal alveolar cells, thrusting them aside so the capillaries lie uncovered in direct contact with the air spaces. If the capillaries in contact with the air and capable of receiving oxygen are too small to support life, the infant cannot survive. An effective method of oxygen therapy increases the percentage of oxygen in the inspired air and thus allows greater absorption.⁶ Many small premature infants have survived in an atmosphere containing 50 per cent oxygen for several months or until they have developed sufficiently to live under normal atmospheric conditions.⁶

Stevenson has made an important clinical application of the use of carbonic anhydrase in disease of the newborn.⁷ The action of this biologic catalyst is to expedite the liberation of carbon dioxide from carbonic acid. Without its influence this gas cannot be unloaded from the blood at a speed commensurate with the rate of pulmonary circulation. This delay indirectly impedes the uptake of oxygen, for which reason oxygen therapy is of no avail. Stevenson found that the concentration of circulating carbonic anhydrase is low in the newborn, and even lower in the premature infant. It is likely to be especially low in such infants as are cyanotic without obvious reason. The mortality rate in these cases is high, but post-mortem examination reveals little cause of death. Certainly, the older notion of congenital atelectasis is fallacious in such cases. When, however, these infants are transfused, their blood enzymes become rapidly elevated and their cyanosis disappears; furthermore, the mortality rate is considerably lowered.

Feeding and energy requirements. Gordon⁸ states that the caloric intake of premature infants during the first few days of life is a matter of no real concern. Even though the caloric intake is zero the total negative energy balance is small since the basal metabolism is only 40 to 50 calories per kilogram per day and the quotas for fecal loss and specific dynamic action, which depends on the food intake, are small. For older premature infants the basal metabolic rate in terms of body weight averaged 58 calories per kilogram per day. The only change in the number of calories per kilogram from week to week was an increase of 5.3 calories from the first to the second week of postnatal life.⁹

The total caloric requirement of premature infants is from 75 to 90 calories per kilogram per day for the first two or three weeks of life, and thereafter 100 to 125 calories.^{10,11}

The premature infants have the power to metabolize carbohydrate as efficiently as do full-term infants.⁹ They also have an ability to absorb protein equal to that observed in full-term infants.¹¹ Many premature infants exhibit a defect in their alimentary absorption of fat, irrespective of the type of fat, but inability of the alimentary tract to split fat is not the determining factor in this defective absorption. Whether the defect in the transport of fat across the intestinal wall is dependent on an anatomic underdevelopment of the capillaries and villi, or a functional impairment of the enzyme mechanisms concerned with phosphorylation of fat or on differences of intestinal motility is a problem reserved for future study. Whatever the mechanism involved, Levine and Gordon¹² are convinced that the failure of some premature infants to thrive on presumably adequate diets may be the result of faulty absorption of ingested fat. These authors recommend a reduced fat content in the diet for premature infants and the maintenance of the total dietary calories at the same level by replacement with protein and carbohydrate. Their feeding mixture contains 120 calories per kilogram of body weight, and the total fluid volume is 150 cc. per kilogram, the basic constituents being 2.5 gm. of fat, 18 gm. of carbohydrate and 6 gm. of protein per kilogram.

Levine and Gordon¹¹ question the assumption that human milk is the ideal food for premature infants. They point out that it is a relatively dilute feeding and it may predispose to increased peristalsis and diarrhea, abdominal distention and respiratory embarrassment. It is relatively high in fat. It is low in mineral content, particularly in calcium and phosphorus, and there is abundant evidence to prove that, even though all the calcium and phosphorus contained in the daily amounts of human milk ordinarily ingested by the premature infant are completely absorbed and utilized, the amounts are still insufficient to meet the demands for bone growth during the first year, as determined by chemical analysis of the bones of fetuses and by studies of mineral retention.¹³ Human milk is relatively low in protein, and it has been shown that augmentation of the protein intake is accompanied by an increased alimentary absorption of the protein ingested. The rapid rate of body growth of premature infants implies the desirability of a correspondingly high protein intake for the manufacture of the needed extra protoplasm.

There are certain arguments in favor of human milk as the ideal food for premature infants. Teleologically, a food supplied by nature is preferable to any form of artificial food. There is suggestive, but not conclusive, evidence that immune substances may be transferred in the breast milk and particularly in the colostrum. Nursing at the breast has many practical and economic advantages. The physiologic and psychologic benefits to the mother

of suckling her infant at the breast cannot be gainsaid. Finally, human milk has a low content of electrolytes and the renal excretion of such substances may be better handled in this form by the premature infant, whose kidneys have been shown to be less efficient excretory organs than those of full-term infants.¹¹

Regarding the relative merits of human and cow's milk as the ideal food for premature infants Levine and Gordon¹¹ suggest that in hospital practice or when human milk is not available except at great expense a cow's milk mixture low in fat is an adequate substitute.

Fluid requirements. Levine and Gordon¹¹ recommend the routine use of relatively low fluid intakes—130 to 150 cc. per kilogram of body weight—in the feeding of premature infants. When fluid intake was below 95 cc. per kilogram large amounts of water were withdrawn from the body, resulting in a negative water balance and dehydration. With higher fluid intakes the infants retained in their bodies a relatively fixed amount and merely eliminated the extra water as extra urine.

Vitamins. The tendency of the premature infant to have hemorrhagic manifestations of a serious nature is explained by the fragility of his capillaries and the low prothrombin content of his blood plasma. The paucity of vascular elastic tissue, the frequent occurrence of anoxia with its deleterious effect on capillary integrity and the low body reserves of vitamin C required for building so-called "cementing substances" are probably the chief factors contributing to the increased permeability of the capillaries of the premature infant.

Levine, Marples and Gordon¹⁴ have recently demonstrated the important role of vitamin C in the intermediary metabolism of protein in premature infants. The action of vitamin C is specific in completing the oxidation of two aromatic amino acids, phenylalanine and tyrosine. A defect in aromatic-amino acid metabolism can be produced at will in premature infants by feeding mixtures of cows' milk containing 5 gm. or more of milk protein per kilogram of body weight and by withholding vitamin C. The defect can be promptly eradicated by the administration of vitamin C in adequate dosage. The authors therefore recommend that all premature infants be given 25 to 50 mg. of ascorbic acid daily from birth and from 75 to 100 mg. daily after feedings of cows' milk have been instituted.

A reduced antenatal storage of calcium, phosphorus and possibly vitamin D predisposes the premature infant to rickets. Added to this predisposition is the defect in fat absorption and presumably in the fat-soluble vitamins, as well as the rapid rate of body growth and the increased demands for retention of calcium and phosphorus, often in the face of a diminished dietary supply provided in human milk. Even if vitamin D is administered and absorbed in adequate amounts, its efficacy in

promoting renal tubular reabsorption of phosphate, which Harrison¹⁵ has demonstrated to be one of the functions of this vitamin in older subjects, may be minimal as a result of the defect in renal function. This impairment, together with faulty alimentary absorption of vitamin D, may explain the high dosage of the vitamin needed to prevent rickets in premature infants.

MISCELLANEOUS CONGENITAL DEFECTS

Warkany¹⁶ has submitted further proof to defend his thesis that certain types of maternal nutritional deficiency can result in specific malformations in the young. The offspring of female rats reared and bred on a diet deficient in the vitamin factor found in pigs' liver produced 32 per cent abnormal offspring. The addition of 2 per cent dried pig liver to the diet prior to the fourteenth day after mating prevented the occurrence of deformities. The defects occurred in the skeletal system and included shortness of the mandible, shortness or absence of the radius, ulna, tibia or fibula and fusion of the ribs and of the sternal centers of ossification. In another experiment Warkany¹⁷ observed congenital skeletal malformations in 45 per cent of the offspring of female rats fed a rachitogenic diet. The changes observed comprised a pronounced curving of the radius, ulna, tibia and fibula, as well as angulation of the ribs, and were quite distinct from those seen in the vitamin B deficient diet. The addition of vitamin D to the maternal diet prevented these malformations. In his most recent communication Warkany¹⁸ describes marked maldevelopment of the eye in the offspring of female rats fed a diet deficient in vitamin A.

New light has recently been thrown on the etiology factors involved in certain congenital malformations by three series of cases reported from Australia in which virus infections, particularly German measles, occurring early in pregnancy seem to be definitely related to congenital defects.¹⁹ Gregg reported a series of 78 patients with congenital cataract, 44 of whom also had congenital heart disease, occurring in infants whose mothers, with few exceptions, had suffered from what was presumed to be German measles in the early months of pregnancy. Swan reported 49 cases of rubella occurring in all stages of pregnancy, of which 25 occurred in the first two months, every one of which showed congenital defects, usually of the eye or heart. In 50 per cent of those having rubella in the third month the infants showed defects. The congenital malformations encountered were 17 heart lesions, 14 defects of the eye, 7 deaf mutes, 1 mongoloid idiot and several cases each of microcephaly, hypospadias and mental retardation. In a follow-up communication Swan added 10 more cases of congenital malformations occurring in infants born of mothers who had had rubella early in pregnancy. Reese reported 3 cases. Erickson¹⁹ added 11 cases

of congenital cataract and congenital heart disease occurring under similar conditions in this country.

Both Swan and Erickson raise the question whether therapeutic abortion is justified if rubella occurs during the first two months of pregnancy, since in the experience of both, 100 per cent of such babies had serious congenital malformations.

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULAS

Esophageal atresia and tracheoesophageal fistulas have formerly been considered incompatible with life. In the last few years, however, a few successes or partial successes have been reported from various parts of the country and it now appears correct that surgical intervention should be attempted. Ladd²⁰ has recently reported 39 such patients operated on at the Children's Hospital, of whom 11 are living. He emphasizes that the surgical approach to combat this condition is subject to change but that, at the present time, primary anastomosis of the esophagus is the operation of choice when the two ends of the esophagus can be approximated without too much tension. In cases in which the ends of the esophagus are far apart, the three-stage operation, with the ultimate construction of an anterior thoracic esophagus, is a safer operation. The last 5 patients operated on according to this plan are living and doing well.

Ladd predicts that, if obstetricians and pediatricians are alert and make an early diagnosis, the mortality will be further lowered.

The diagnosis may be suspected when the newborn infant has an excess of mucus or saliva in the mouth, with or without an associated cyanosis. The next suggestive symptom is vomiting of mucus even though no food or fluid has been given, or vomiting after the first feeding. It is essential to a good prognosis, however, that the diagnosis be made before food is given, since its presence in the lung will probably result in a pneumonia. On the least suspicion, a stiff catheter should be passed down the esophagus in order to demonstrate a blind pouch. If in doubt x-ray films should be taken with the catheter in place. Barium should not be given, since its presence in the lung results in an inflammatory reaction; if an opaque medium is needed it is much safer to use lipiodol. The presence or absence of rales in the lungs and of air in the intestinal tract depends on the type of anomaly present.

SPINA BIFIDA AND CRANIUM BIFIDUM

Ingraham and Swan²¹ have analyzed 546 infants and children seen at the Children's Hospital during the last twenty years to see whether there can be established any reasonably definite criteria for prognosis, for operative therapy and for operative technics. They also wished to discover if the general attitude of hopeless pessimism toward these cases should not be modified by examination of the end

results. The authors found that 30 per cent of the patients with spina bifida and 34 per cent of those with encephalocele may expect a relatively normal life. They concluded that an unduly pessimistic prognosis is unwarranted until individual evaluation has been carefully pursued.

Ingraham and Scott²² have also presented a series of 20 cases with the Arnold-Chiari malformation to emphasize that this is not a rare condition but is a frequent accompaniment of myelomeningocele. This malformation is a congenital anomaly of the hind brain characterized by a downward elongation of the cerebellum and brain stem into the cervical portion of the bony spinal canal. Surgical treatment should be limited to patients without extensive paralysis of the lower extremities and sphincters. It should not be offered if hydrocephalus is so advanced that it is inconsistent with normal mental development. The authors believe that encephalography may help in identifying the associated microgyria, which is probably another contraindication to operation.

CONGENITAL CEREBRAL PALSY

Until twenty-five years ago Little's disease or congenital cerebral palsy was held to be the result of various factors, chiefly birth trauma, acting during birth on the central nervous system. Of late, doubt concerning the prime etiologic role of birth trauma has arisen because of post-mortem examinations that failed to show any evidence of birth trauma and because there was a high incidence of essentially normal birth histories in these cases. Yannet²³ analyzed 86 patients in whom the diagnosis of congenital cerebral palsy had been made and uncovered data showing the major importance of developmental cerebral defects in the etiology, as well as information on certain genetic relations. Yannet found the average age of the mothers at the time of birth of the affected child was significantly greater than that of child-bearing women in the general population. The affected children tended to have a later ordinal birth rank than would be normally expected. There was a significant incidence of similarly affected siblings of patients with cerebral palsy. The incidence of mental deficiency in the nonaffected siblings was greater than would be expected from random selection. Finally, there was an unusually high incidence of associated physical defects, especially those involving the eyes.

ERYTHROBLASTOSIS FETALIS

The pathogenesis of erythroblastosis fetalis has been established in great measure through the brilliant work of Philip Levine, who has recently published an excellent review of the subject.²⁴ Erythroblastosis fetalis is caused by isoimmunization of the mother by a dominant hereditary blood factor in the fetus, most frequently the Rh (rhesus) factor. This intrauterine hemolytic disease of the

fetus and the newborn infant occurs under highly specific conditions, determined by the presence or absence of the Rh factor in the parents. In more than 90 per cent of the cases the father's blood contains the Rh factor (Rh+), the mother's blood lacks the factor (Rh-) and the fetal blood possesses it (Rh+). The two essential steps in the pathogenesis of erythroblastosis fetalis are the response of the Rh- mother to the Rh+ fetal blood by production of anti-Rh agglutinins and the continuous passage of maternal anti-Rh agglutinins through the placenta to react with and hemolyze the susceptible fetal Rh+ blood.

In 1940, Landsteiner and Wiener studied the specificity of an immune serum produced in rabbits and guinea pigs by injections of the blood of *Macacus rhesus*. This serum was found to agglutinate 85 per cent of all human bloods. These bloods were termed Rh+, and the 15 per cent inactive bloods, Rh-. The experimental anti-Rh serum produced by rabbits or guinea pigs cannot as yet be used as a routine diagnostic serum, since the resulting agglutinations are unreliable or difficult to read. For Rh typing one has had to depend, until recently, on high-titer human serum, which is found in only about 1 of 20 mothers of erythroblastotic infants. Since the Rh factor is a mosaic composed of several antigenic substances, not all the human anti-Rh serums in contrast to anti-A or anti-B testing serums, give parallel reactions.²⁴ There are, as a result, three main types of human anti-Rh serums: that agglutinating 87 per cent of random bloods and called "anti-Rh" by Wiener and Landsteiner; that agglutinating 85 per cent of random bloods, called "anti-Rh"; and that agglutinating 73 per cent of random bloods, called "anti-Rh₁." It is therefore possible to have a small number of cases of proved erythroblastosis fetalis in which evidence of isoimmunization (father Rh+ and mother Rh-) cannot be obtained provided that human serum of the anti-Rh₁ type is used.

The important problem of accurate Rh typing appears to be solved by the timely work of Diamond²⁵ at the Children's Hospital. Working in co-operation with the Department of Physical Chemistry of Harvard Medical School, he has been able to pool and concentrate low-titer anti-Rh serums, obtaining a globulin fraction that yields accurate typing results. Furthermore, the technic of typing is simple. It consists in mixing a drop of the concentrated anti-Rh serum with a drop of the unknown red-cell suspension on a glass slide and observing at once the presence or absence of agglutination.*

*The Blood Grouping Laboratory, 300 Longwood Avenue, Boston 15, is in need of more anti-Rh typing serum for the armed forces and civilian use. Physicians and hospitals are urged to send to the laboratory a few cubic centimeters of blood from any patient known to have had a baby with erythroblastosis delivered within the last two years. If the serum is found to contain a useful amount of anti-Rh agglutinins, the physician or hospital will be notified and requested to forward from 100 to 500 cc. of the patient's blood. Seventy per cent of the concentrated serum will be set aside for the military services and 30 per cent will be available immediately to the contributing physician or hospital in the form of standard anti-Rh typing serum.

The demonstration of Rh isoimmunization is possible in 90 per cent of the mothers of erythroblastotic infants, but in 10 per cent the mothers are Rh+ and some other cause for the syndrome must be found. Levine²⁴ suggests that there should be other blood factors besides the Rh factor capable of inducing isoimmunization. He was able to prove this point by demonstrating atypical agglutinins produced by two Rh+ mothers of erythroblastotic infants; both serums agglutinated all Rh- bloods but did not react with other Rh+ bloods. Since this new factor had some genetic relationship to the Rh factor, Levine suggested the two letters Rh be reversed, the terms "Hr" and "anti-Hr" being used to designate this new blood factor and its corresponding antibody. The Hr factor, however, can be held responsible for isoimmunization in only some of the Rh+ mothers. In a certain number of the remaining cases, isoimmunization may perhaps be induced by the factors A or B in fetal blood. In a few cases no cause for the isoimmunization could be demonstrated by present methods. It must be remembered that in some cases a clinical syndrome indistinguishable from erythroblastosis fetalis may be the result of fetal anoxia, syphilis or septicemia.

Potter²⁶ insists that, to diagnose erythroblastosis anemia, erythroblastemia and splenomegaly must be present. Other manifestations usually associated are edema, jaundice, hepatomegaly and placental hypertrophy. It is important to stress these diagnostic features, since the diagnosis of erythroblastosis fetalis is being made too widely and on insufficient evidence on the one hand and is still being overlooked on the other.

In approximately 12 per cent of all marriages the wife is Rh- and the husband is Rh+. If the father is homozygous, all the offspring will be Rh+; if he is heterozygous, there is a 50 per cent chance that the infant will be Rh-. Thus, in approximately 9 per cent of all births an infant with Rh+ blood is delivered of a mother with Rh- blood, but erythroblastosis actually occurs in only 0.1 to 0.2 per cent of all pregnancies. The Rh typing of all pregnant women is recommended, but as a result, 120 out of every 1000 couples may be upset, even terrified, at the possibility of a forthcoming erythroblastotic infant. In all fairness the reassuring fact that this is to be expected in less than 2 per cent of such matings should be emphasized. Furthermore, even should an erythroblastotic infant be found at delivery the ultimate outlook for over half of these patients is excellent.

The pathogenesis of this disease is still far from being completely solved. The Rh factor must play an important role, but one wonders why erythroblastosis fetalis occurs in only about 2 per cent of the Rh+ infants whose mothers have Rh- blood. It is obvious that there must be other unknown factors in the equation.

The termination of pregnancy by cesarean section as soon as the fetus becomes viable has been recommended in such cases, on the assumption that if the fetus can be delivered early enough in the course of pregnancy it may escape being affected by maternal agglutinins.^{26,27} It has also been suggested that the mother's blood be watched closely for the appearance of agglutinins or for a rise in agglutinin titer and that the pregnancy be terminated at the time when agglutinins appear or when the titer suddenly rises.²⁸ If there were no hazard associated with prematurity, early delivery might be an advisable procedure on the supposition that the more prolonged the exposure to anti-Rh agglutinins, the more severe the disease. The fetus, however, is probably affected early in pregnancy, regardless of whether demonstrable agglutinins are present in the maternal circulation; furthermore, many infants become much more severely affected immediately after delivery than they were during intrauterine life. Too few cases have as yet been reported to indicate whether early delivery with the consequent discontinuation of direct exposure to anti-Rh agglutinins can outweigh the handicap of prematurity imposed on an infant already suffering from erythroblastosis. At the Chicago Lying-in Hospital, as well as in other clinics, infants have been delivered early by cesarean section only to die of erythroblastosis despite the administration of blood at birth, and it has been concluded that nothing is to be gained by premature delivery.²⁶

In the obstetric management of the mother of a potentially erythroblastic infant it is unfortunate that there is no direct connection between the presence or absence of anti-Rh agglutinins in the maternal serum and the condition of the infant. Levine²⁴ failed to find anti-Rh agglutinins in more than 50 per cent of the mothers, although he quotes British workers as observing a higher incidence. He states that isoimmunization may occur even in the absence of demonstrable antibodies. Neither the presence or absence of anti-Rh agglutinins nor the titer of these agglutinins is a reliable index of the presence or severity of erythroblastosis in the infant.

The treatment of erythroblastosis fetalis is by transfusion of Rh- blood from a donor other than the mother.

INFECTION

In spite of increased knowledge regarding causes of infection in newborn infants and methods of prevention, epidemics still occur. Reports coming to the Children's Bureau indicate that they are increasing along with overcrowding of the maternity services. In a number of hospitals in different localities epidemics of diarrhea among newborn infants have been associated with mortality rates of from 30 to 50 per cent.² *Standards for Care of Newborn Infants and Plans for Hospital Nurseries*, two booklets issued

by the Children's Bureau and previously referred to, give valuable suggestions to assist in the prevention and control of all types of infection in the newborn.

Torrey and Reese²⁹ have found that the initial aerobic bacterial flora of the throat and nasopharynx of artificially fed newborn infants is largely acquired through direct contact with adults and not from the parturient canal. Droplets of saliva comprise the principal vehicle of transfer. The flora in premature infants is essentially the same as that in full-term infants of similar age. Although occasional contact with adult carriers of pneumococci, influenza bacilli and beta-hemolytic streptococci occurred, the first two organisms were not present and the streptococci were only rarely present in infants from one day to four weeks old.

These authors found that up to sixteen hours after birth the nasopharynxes and throats of 80 per cent of the infants exhibited sterility. Between twenty-four and forty-eight hours after birth 50 per cent of infants in wards exposed to ultraviolet irradiation still showed sterility, as contrasted with only 12 per cent of infants in wards not so exposed. Beyond that time results for the two groups were essentially alike, except in regard to hemolytic strains of *Staphylococcus aureus*. Ultraviolet irradiation did not retard the acquisition of nonhemolytic streptococci but did delay the presence of hemolytic strains of *Staph. aureus*; in the absence of ultraviolet irradiation an occasional air-borne transfer of the latter organism probably occurred.

Torrey and Reese conclude that ultraviolet irradiation does not prevent person-to-person transmission of pathogens through the air within the range of a few feet. Among infants from seven to twenty-five days old in wards without irradiation, 60 per cent were carriers of hemolytic strains of *Staph. aureus* in the nasopharynx, of which 86 per cent were coagulase positive and potential pathogens.

These workers also found that the strains of streptococci and of *Staph. aureus* normally present in the throats and nasal passages of adults passed to some extent through all types of face masks, even in the absence of coughing and sneezing. It should be pointed out, however, that they used a four-layer gauze mask in their study and not the more efficient mask with an inner layer of sheet cotton. Abramson³⁰ thinks that the use of the face mask in the control of droplet infection is an important integral part of preventive nursing and medical care, even though it is believed that such masks have an efficiency of only from 50 to 75 per cent. The criticisms of expense, difficulty in supplying and laundering and the tediousness of application are not valid arguments when reckoned in terms of protecting the lives of babies. Far from abandoning the face mask, efforts should be directed toward more efficient ones. The use of sheer-gauze masks

and of the paper masks should be eliminated in favor of those of more adequate construction, such as the absorbing or the deflector variety.

Epidemic diarrhea of the newborn. The recognition of epidemic diarrhea of the newborn is recent, most of the literature relating to it having appeared within the past decade. In general, the epidemics have had a significant mortality rate.

One of the problems in the control of epidemic diarrhea is the establishment of the diagnosis. Often the first cases develop so insidiously that the possibility of epidemic diarrhea is not considered and proper isolation is not provided until many other infants in the nursery have been exposed to the infection. Anderson and Nelson³¹ recognize that there is often a tendency for loose and frequent stools, that overfeeding and improper artificial feeding may cause loose stools, that breast-fed babies frequently have stools postprandially, that drugs, laxatives and food irritants ingested by the lactating mother may cause loose stools in the infant and that parenteral infection or an enteritis due to dysentery organisms may be the cause of diarrhea. In order to protect other infants, however, they advise the isolation of an infant with diarrhea whenever any of the aforementioned conditions cannot be readily incriminated, as well as the provisional diagnosis of epidemic diarrhea of the newborn whenever two or more infants are similarly affected.

Tyson³² finds it difficult to decide whether epidemic diarrhea is a disease entity in itself or part of a symptom complex. In three epidemics he observed, three different organisms were cultured from both the stools and the blood stream — *Streptococcus haemolyticus*, *Pseudomonas aeruginosa* (pyocyaneus bacillus) and *Escherichia coli* (colon bacillus).

Although a virus etiology for many of the epidemics of diarrhea in the newborn has been suspected it remained for Buddingh and Dodd³³ to demonstrate a virus in one epidemic. These authors had been studying a stomatitis of infants and children that was often accompanied by diarrhea and had demonstrated a hitherto unrecognized virus isolated from the mouths and stools by inoculation of the scarified rabbit cornea. In October, 1943, one of a pair of premature twins in a nursery was found to have stomatitis and diarrhea. Within the next few days several other infants developed the infection. In spite of immediate strict isolation precautions, 16 of the 30 infants in the nursery developed diarrhea within the course of the next two weeks. Although a mild stomatitis was present in 10 of the 16 infants, the outstanding feature of the diseases was diarrhea. Swabs obtained from the mouths and stools of all the affected infants produced characteristic lesions when inoculated upon the cornea of a rabbit. Swabs from the 14 unaffected babies produced no lesion.

Mouth swabs from 3 of the 4 nurses in charge of the nursery were also found to be positive for the virus. Two of the nurses at no time had lesions in

their mouths, but the third developed stomatitis during the week following the outbreak of diarrhea in the nursery. She carried the infection home to her own children, who were six and eight years old, and three months later her mouth swabs were still positive for the virus. Mouth swabs from 2 of 60 adults who were more or less directly engaged in caring for children in the nurseries and pediatric wards were positive for the virus without any accompanying symptoms. One of these carriers was an intern who had taken charge of the nursery after the epidemic of diarrhea had ceased. Four days later 3 new cases of stomatitis and diarrhea developed. Substitution of this intern for another, known to be free of virus, and isolation of the 3 infants controlled further spread of the disease.

When confronted with the possibility of an epidemic of diarrhea in the newborn, time is a factor and treatment cannot wait for the results of laboratory investigation. The plan of treatment at both the Boston Lying-in and Children's hospitals³⁴ calls for an immediate threefold system of isolation: physical isolation of infected patients; physical isolation of all contacts; and physical isolation of all new admissions from contact with either of the two preceding groups. Active treatment of infected patients is based on the suggestions of Twyman and Horton,³⁵ which are as follows: succinylsulfathiazole (sulfasuxidine) 1 gr. per pound of body weight per day; opiates by mouth; vitamin K, plasma or whole-blood transfusions; parenteral fluids; and protein milk formulas. In addition to the above procedures the infants are given from 12,000 to 24,000 units of penicillin per day in divided doses every three hours. The rationale of this treatment is that the sulfasuxidine combats enteric infection, if present, that the penicillin combats parenteral infection, if present, and that, if the disease proves to be of virus origin, nothing of a specific nature can be done beyond the general supportive measures outlined. The justification of this "shot-gun" approach is the high mortality associated with diarrheal disease.

In the epidemic of diarrhea of the newborn studied by Anderson and Nelson³¹ a low carbon dioxide combining power of the blood was observed in 50 per cent of the cases in which abnormal clinical manifestations were noted, in spite of the fact that most of these infants did not exhibit the classic picture of acidosis. Significant clinical improvement attended the correction of the acidosis by the parenteral administration of a 5 per cent solution of sodium bicarbonate or of a 1M/6 solution of sodium lactate.

They emphasized the importance of constant observation of the ill infants and on the determination of the carbon dioxide level of the blood whenever there are evidences of increasing severity of the disease, with or without the usual manifestations of acidosis. 1101 Beacon Street

CASE 31021

PRESENTATION OF CASE

A fourteen-year-old boy was admitted to the hospital because of abdominal pain and convulsions.

Three weeks prior to admission, while playing football, he was kicked in the right eye. Although he felt dizzy, he did not lose consciousness and was able to resume play. His eye subsequently became swollen and ecchymotic. During the following week he complained a good deal of abdominal discomfort and took soda for relief. About a week later, one week before entry, he was awakened from sleep by severe abdominal pain accompanied by nausea and vomiting. He was given an enema and on getting out of bed appeared confused and unable to find the door. While straining to expel the enema he suddenly became stiff, breathless, cyanotic and then limp and unconscious. He regained consciousness after five minutes. He was not incontinent and did not bite his tongue. There was no headache following the seizure, and he had no recollection of what had occurred. He was admitted to a community hospital where four similar attacks occurred during the next twenty-four hours. He vomited large amounts of dark-brown material. Although he failed to move his bowels for three days, an enema at the end of that time produced good results. The white-cell count was reported to be 19,000, and a roentgenogram of the abdomen was said to show dilated loops of small intestine. He was transferred to this hospital for study.

Physical examination revealed a pale, lethargic but oriented boy in no acute distress. There was slight ecchymosis around the right eye. The pupils, ocular movements, visual fields and fundi were normal. The heart and lungs were negative. The abdomen was tense, distended and tympanitic, with some tenderness and audible peristalsis in the lower abdomen. Neurologic examination was essentially normal.

The temperature was 99.2°F., the pulse 118, and the respirations 20. The blood pressure was 140 systolic, 80 diastolic.

Examination of the blood revealed a hemoglobin of 12.8 gm. per cent. The urine had a specific

*On leave of absence.

gravity of 1.022, with a + test for albumin; the sediment contained an occasional red and white cell and a rare hyaline cast per high-power field. The blood serum nonprotein nitrogen was 23 mg. per 100 cc., and the protein 6.4 gm. per 100 cc., with an albumin-globulin ratio of 2.6; the serum chloride was 86 to 96 milliequiv. per liter. A blood Hinton test was negative.

Roentgenograms of the abdomen revealed several dilated loops of small bowel extending across the midabdomen. Considerable gas was seen in the colon but none in the rectum. A barium enema passed without delay from rectum to cecum and revealed no abnormality of the colon. The appendix was negative. The terminal ileum filled for a distance of 5 cm., at which point the barium column terminated rather abruptly: a post-evacuation film showed moderate contraction of the colon, but no further retrograde passage of barium in the terminal ileum. An x-ray examination of the skull was negative.

A Miller-Abbott tube was inserted into the duodenum with some difficulty and several hundred cubic centimeters of fluid was aspirated. After intubation, x-ray films failed to reveal the dilated loops of small bowel previously observed. The nausea and vomiting continued; the urine output was low, and fluids were administered parenterally. Except for the expulsion of the barium enema, the patient did not move his bowels after entry into the hospital. On the night of the fifth hospital day he awakened suddenly with a cry and complained of burning pain in the upper abdomen accompanied by a bearing-down sensation as if he wanted to move his bowels. The temperature rose to 102°F., and the abdomen was boardlike and acutely tender. An emergency laparotomy was performed that night.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: May we see the x-ray films before we start the discussion?

DR. MILFORD SCHULZ: This film, taken shortly after entry, shows the dilated loops of small bowel. There is a little gas in the colon here and there, but the colon is not dilated. On the film made after filling the colon with barium, you can still see the gas in the bowel; the small bowel is dilated but the terminal ileum is not. It is interesting that the appendix, which is filled, apparently is movable—at least the relation between the appendix and the cecum changed following evacuation. In the film taken three days later there is still a residue of barium in the bowel and most of the small bowel has been deflated.

DR. CHESTER M. JONES: Where is the Miller-Abbott tube? In the upper ileum?

DR. SCHULZ: I should say that it was either in the proximal ileum or in the distal jejunum.

DR. ALLEN: I wonder how he knows that.

DR. JONES: That is what I wonder.

DR. SCHULZ: It is not in the distal ileum because it is not near the cecum and there is quite a bit of tube present for it to be in the proximal jejunum.

DR. JONES: I agree.

DR. ALLEN: Having just listened to an excellent discussion of a patient who had two lesions,¹ one wonders whether, by any chance, luck will hold and whether this boy also had two conditions. It is difficult for me to connect his apparently minor injury to the orbit during a football game with the gastrointestinal story. When I first read the abstract I thought that this might well have been a serious injury to the head and that this boy might have had a Cushing syndrome of peptic ulcer on a central-nervous-system basis. As I read farther I thought that he might conceivably have had a peptic ulcer associated with a Meckel's diverticulum containing gastric mucosa. During the week following injury he had a sufficient amount of abdominal discomfort to take soda, and it says "for relief" not "with relief"; one wonders whether this boy did have something that caused gastric hyperacidity.

He got on extremely well, however, until about a week later, that is, two weeks after injury and one week before entry, when he was awakened from sleep by severe abdominal pain accompanied by nausea and vomiting. If he had an ulcer of the stomach that had actually perforated he certainly would have been awakened from sleep. He might have been nauseated and he might have vomited, but it does not appear that he was quite ill enough or that the onset was quite sudden enough for it to be a perforation of an ulcer.

The fact that he was confused following an enema and then had a so-called "convulsion,"—he is said to have become stiff, breathless, cyanotic and then unconscious,—is not particularly helpful because a considerable number of people faint after an enema. It is not unusual for persons to be confused in the middle of the night if they are sleepy, and they might even take the wrong turn and go through the wrong door under these circumstances. We had a man brought in here a few years ago who had just returned from his summer place, where the bathroom entrance was to the left; on arising at night, he, out of habit, turned in this direction instead of to the right, where his town-house bathroom was located, and stepped into an elevator well, falling four flights.

The patient we are discussing here was admitted to a community hospital and had four similar attacks. I suppose that means that he had four periods of unconsciousness. I do not know whether the phrase "similar attacks" means that he also had an enema and severe pain, but I assume that he did not have an enema each time he lost consciousness. He did vomit large amounts of dark-brown material. That may be significant since, if he had a perforated viscus, he would not vomit

large amounts of this material unless the perforation was low in the gastrointestinal tract. It is possible that this dark-brown material contained blood, because a patient who is vomiting a good deal will have a certain amount of bleeding from the mucous membranes. On the other hand one wonders if, by any chance, this was small-bowel content that was being vomited. The fact that the enema at the end of three days produced a good result from the colon is of no help except to say that the disease was not in the colon. It only means that he had an accumulation of fecal matter in the colon that had been there prior to the acute illness and that the enema removed some of this fecal material. During the period that he was in the community hospital the white-cell count was said to have been 19,000. We have no mention of white-cell counts after admission here, but I am sure that they were done and should like to know what they were.

DR. BENJAMIN CASTLEMAN: None are recorded.

DR. ALLEN: Of course they were done, but sometimes they do not get recorded. At any rate I shall assume that the count before entry was a comparatively correct figure. It is reasonable to suppose that a secondary inflammatory process was going on, some process that was damaging or at least impairing the blood supply to some segment of the bowel. I suspect that the increased white-cell count was not due to the "black eye."

The physical examination does not help us much, except that at the time he was examined he was not in acute distress, which means that he did not have a continuing process but something that came and went to some extent. That practically rules out the possibility of his having a perforation of a high viscus, unless one can conceive of a perforation that sealed itself off and reperforated; I doubt that this could recur so many times as is described here.

We shall have to accept the fact that neurologic examination was essentially normal. I do not know whether "essentially" is put in for a reason or whether it was entirely normal. There is one small fact—a systolic blood pressure of 140 is abnormally high for a boy of fourteen. He had a slight amount of albumin in the urine and an occasional hyaline cast, both of which might go with an illness of this severity; also there was abnormality in the albumin-globulin ratio, which could have been due to dehydration. The chloride was slightly low.

We know from the roentgen films of the abdomen that he had small-bowel obstruction of some sort. From the film after the barium enema I have to deduce that the obstruction was fairly low in the ileum; the barium certainly stops short at that point as if there were a string around the bowel, or a tumor or gallstone blocking it in that region. It might have been due to a tight band across the bowel. Certainly this is an extremely sharp demarcation in the barium column and therefore suggests a complete, total obstruction at that point.

The patient was observed for a period of five days and did well with Miller-Abbott decompression of the small intestine. We now have reached a point nine days after the acute onset of the abdominal difficulty and four weeks after the football injury, and it is difficult for me to visualize any injury to the abdomen that took place in the football game that would produce this picture. It is also difficult for me to associate the minor injury to the orbit with anything going on later, particularly with a negative neurologic examination and a negative skull plate. So I believe that this sudden episode that happened on the night of the fifth hospital day was something different, probably a complication of the intestinal obstruction. I assume that the sudden pain with a bearing-down sensation was due to a perforation in this region or at least to an extravasation of fluid into the pelvis, since this type of irritation is sometimes seen in acute episodes. Often when an acutely inflamed appendix is lying in the pelvis a patient has exactly this same bearing-down feeling, a desire to move the bowel, usually with no relief.

So in summing up this case I believe that this boy's football injury had nothing to do with his abdominal difficulty. He did have a contusion to his orbit, but he coincidentally began to get into gradual difficulty with his abdomen; this was something rather severe that ended in total small-bowel obstruction in the region of the terminal ileum. This picture probably could not be due to a Meckel's diverticulum. If this boy had an inflammatory process from a Meckel's diverticulum, there would almost surely be a tendency to fill some of the terminal ileum after evacuation of the barium enema. I do not know what could cause this sudden obstruction, but I think that there are two possible explanations. One is that he had a band of adhesions across this area that produced obstruction at this point. I should expect, however, if that had been the case, that he would not have got along so well as he did for the first four days of his illness, that is, before the Miller-Abbott intubation. The only other thing that I can think of to explain such a picture in a boy of this age—obviously it could not have been gallstone ileus, at least I do not believe that it could have been—is that he had an intussusception of the terminal ileum, which is most unusual. Ordinarily intussusception occurs from the ileum into the cecum, but small-bowel intussusception has been reported: Dr. Harvey Stone,² of Baltimore, has recently reported a case in which a polyp of the small intestine produced intussusception of the small bowel with obstruction. I believe that is a likely possibility in this case. I can go no farther, however; I believe that the football injury and the small-bowel obstruction were independent.

DR. LELAND S. MCKITTRICK: Dr. Schulz, would the abrupt cessation of the barium in any way sug-

gest that the obstruction was due to intussusception?

DR. SCHULZ: Ordinarily, the barium runs around the intussusceptum for a short distance or one can see the leading tumor in the barium. Usually it does not cut off so abruptly as this.

DR. ALLEN: This boy probably had an unusual amount of edema around the area, owing to the four days of obstruction prior to the barium enema.

DR. SCHULZ: Yes; I presume that it would take some effort to cause barium to run through such an area of intussusception.

DR. ALLEN: Do you often see an area as completely trapped as the one shown here?

DR. SCHULZ: It is possible. Will a diverticulum loop itself around the bowel?

DR. ALLEN: Yes. A diverticulum can do almost anything. Most of the patients with Meckel's diverticulum are operated on under the diagnosis of intestinal obstruction.

DR. CASTLEMAN: But the obstruction is higher up.

DR. ALLEN: Yes, but usually close to the ileocecal valve. I do not believe that it was a diverticulum.

DR. CASTLEMAN: Dr. McKittrick operated on this boy. Will you tell us about your findings?

DR. MCKITTRICK: As Dr. Allen has said, this case was puzzling. We followed through essentially the same line of reasoning, but since we were not up before a clinicopathological conference, we did not have quite the same urge to explain the cause of an obstruction that was obvious when one saw the x-ray films. We had a little trouble with the Miller-Abbott tube, but it did pass the pylorus and did a good job of deflating him. On the afternoon before operation, the abdomen was quite soft and nontender, and I thought that he was doing extremely well. I was called at about four o'clock the next morning because the patient had been awakened by sudden pain. I came down and operated on him with a working diagnosis of acute small-bowel obstruction with perforation. We had not committed ourselves to the cause of the obstruction.

There was a slight delay in getting under way, through no fault of anyone in particular, but it was approximately two hours after the perforation when the abdomen was opened. The peritoneal cavity did not contain so much fecal material and intestinal contents as I had anticipated. There was widespread purulent material and obvious generalized peritonitis. A distended edematous small bowel presented itself, and by putting the hand into the abdomen I could feel the point of obstruction. As gently as I could I lifted it out and saw two open ends, the small bowel being completely divided. How much of that I had done and how much had been done in the small hours of the morning I do not know. It is quite possible that the balloon of the Miller-Abbott tube saved this boy's life by preventing the escape of the small-bowel contents into the abdominal cavity. It not only had deflated the obstructed segment but the tube, being still inflated

and located 5 cm. above the perforation, had acted as a cork to prevent complete emptying of the bowel into the peritoneal cavity.

We, too, were intrigued by the abrupt cessation in the passage of barium. We did not know what it meant. At operation the obstruction was well above the ileocecal valve and had nothing to do with the x-ray finding.

DR. ALLEN: That was the red herring.

DR. MCKITTRICK: There were lymph nodes up to 1.5 cm. in diameter and a great deal of edema. I thought that the boy had a tumor of the small bowel that had ulcerated through. We resected the segment of ileum and did an end-to-end anastomosis, closing the abdomen without drainage. He was given sulfadiazine intravenously. A pelvic mass developed but cleared up without operation. The wound remained clean, and he had an uneventful convalescence. I should like to re-emphasize the fact that the Miller-Abbott tube with the distended balloon going to the point of obstruction and occluding the outflow of material from above probably saved this boy's life.

CLINICAL DIAGNOSIS

Acute small-bowel obstruction, with perforation.

DR. ALLEN'S DIAGNOSIS

Subacute small-bowel obstruction, with gangrene and perforation, probably from intussusception.

ANATOMICAL DIAGNOSIS

Ileoileal intussusception, with gangrene and perforation.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The specimen we received showed a large porky mesentery, as Dr. McKittrick mentioned, which was composed of inflammatory edematous fat. The tumor-like mass in the ileum proved to be an intussusception of 7 cm. of the ileum, which had become gangrenous. That is why it broke in half. I believe that the boy had it at the time of the first attack of abdominal pain, three weeks before he was operated on, and that that accounted for the extreme necrosis of the bowel, which was black.

DR. MCKITTRICK: I just asked Dr. Allen if he had ever seen an intussusception of the ileum without something to lead it.

DR. CASTLEMAN: We sectioned the entire specimen and could find no evidence of tumor. It is possible that there had been a polyp, but the bowel had become so gangrenous that we could not recognize it.

DR. ALLEN: It might have sloughed off.

DR. CASTLEMAN: That is possible, but there were no polyps elsewhere in the specimen.

DR. ALLEN: I would like to take issue with you on the statement that this intussusception had

existed for four weeks. It is possible to get dead gut in a matter of four days. Is it not possible that this boy had intermittent intussusception during the first three weeks of his sickness, which was at least two weeks before he finally became completely obstructed? His complete obstruction, I believe, dates from the night he was awakened with the severe abdominal pain.

DR. CASTLEMAN: I think that is true. I did not mean that he had complete obstruction for four weeks but that he had intermittent intussusception during this period, with frequent injuries to the ileum in the region of the intussusception.

DR. JONES: Can you recall how many cases you have had with true ileal intussusception without a tumor?

DR. CASTLEMAN: It must be extremely rare. I do not recall another case, but as Dr. Allen mentioned, the tumor may well have sloughed off.

CASE 31022

PRESENTATION OF CASE

A forty-three-year-old woman was admitted to the hospital with dysphagia and headache.

The patient was in apparent good health until two and a half months prior to admission, when she noted difficulty in swallowing liquids. Attempts to drink milk, for example, were followed by choking and she had difficulty in getting her breath. The dysphagia was not always present, and she apparently had no difficulty in swallowing solid foods. She also noticed that her voice was weak and hoarse. Lying down at night brought on a feeling of oppression in the chest, which was not relieved by sitting up. A sense of obstruction was present in the throat, resulting in constant unproductive attempts to clear the throat. There was no cough or expectoration. Three weeks before entry she developed a severe pounding headache aggravated by motion. It was worse in the morning, often beginning as a generalized throbbing and finally localizing in the right temple. Two weeks prior to admission she noted marked weakness of the right arm and was unable to control its movement when reaching for things. The legs felt stiff, and she seemed unable to lift them. Sharp pains were present in the left leg. About four months before admission the patient had several episodes of pain and fullness in the epigastrium that came on about an hour after meals. The distress was relieved to some extent by a hot-water bottle but not by food. A local physician made a diagnosis of gastric ulcer by fluoroscopy. Following treatment the symptoms

disappeared, and at the time of admission she had been free of epigastric distress for three months.

Physical examination revealed a poorly developed, emaciated and dehydrated woman with a weak, hoarse voice. The breasts were poorly developed but otherwise negative. There was no adenopathy. The pupils reacted to light and accommodation. The gait was shuffling. The Romberg sign was positive. The right shoulder drooped and could not be raised; the muscles of the right shoulder and upper arm showed hypotonicity and some atrophy. There was a tendency toward "winging" of the right scapula. All the deep tendon reflexes were hyperactive, more so on the right. The right lower abdominal reflex was diminished. The plantar responses were flexor in type bilaterally. The finger-to-nose and heel-to-knee tests showed awkwardness and overshooting bilaterally, but more so on the right.

The temperature was 98.6°F., the pulse 94, and the respirations 20. The blood pressure was 116 systolic, 70 diastolic.

Examination of the blood showed a red-cell count of 4,520,000, with 14 gm. of hemoglobin, and a white-cell count of 8500, with 60 per cent neutrophils. The urine and stools were negative. The serum protein was 6 gm. per 100 cc.; the blood sugar and the serum nonprotein nitrogen were normal. A tuberculin test in a dilution of 1:1000 was negative. A Hinton test was negative.

A roentgenogram of the chest revealed a few linear shadows in the left third and fourth interspaces anteriorly. An ill-defined shadow was present in the region of the left hilus. An x-ray examination of the skull was negative. Two electroencephalograms taken soon after admission revealed a diffuse spotty dysrhythmia without consistent focal distribution but generally worse toward the occiput.

A lumbar puncture revealed clear colorless fluid. The pressure was normal initially and responded normally after jugular compression. No cells were present; the protein content was normal, and the Wassermann test was negative. An examination of the larynx revealed complete paralysis of the left vocal cord, which lay in the so-called "cadaveric position." The right cord functioned normally.

On the twentieth hospital day the temperature gradually began to rise, reaching 102°F. over a period of about thirty-six hours. She developed some cough, raising a small amount of sputum, and there was pain over the left anterior chest on coughing. The left apex and upper chest were dull to percussion, with bronchial breath sounds anteriorly and an expiratory grunt. There were coarse rales over the left apex posteriorly. The liver was palpable two fingerbreadths below the costal margin. A sputum culture revealed alpha-hemolytic and a few beta-hemolytic streptococci, and a blood culture was negative. The white-cell count was 24,000. A catheterized urine specimen was negative. A roentgenogram of the chest revealed irregular patchy

consolidation of the left upper lobe and a small amount of fluid in the posterior costophrenic sinus.

The temperature continued to range between 100 and 102.6°F. Respirations were shallow and rapid, and the patient appeared dehydrated and slightly cyanotic. She was treated with sulfadiazine and oxygen. On the twenty-sixth hospital day, the patient became jaundiced and a moderate amount of bile appeared in the urine. Sulfadiazine was stopped and penicillin substituted. She was also given potassium iodide because of difficulty in bringing up the tenacious sputum. Diffuse coarse rales were audible throughout the lung field.

On the thirtieth hospital day the patient began to improve. The temperature gradually fell to normal, and the sputum diminished in quantity. The icterus cleared completely, and the liver was no longer palpable. The lungs showed slight dullness over the entire left chest, with scattered fine and coarse rales, and normal breath sounds diminished over the left apex anteriorly. There was slight sacral edema. The total plasma protein was 5.3 gm. per 100 cc., with an albumin-globulin ratio of 0.93. The serum chloride was 90 milliequiv. per liter. A cephalin flocculation test was negative in twenty-four and \pm in forty-eight hours. X-ray examination of the chest revealed little change in the appearance of the left upper lobe.

The temperature continued to range between normal and 100°F., occasionally reaching 101°F. The neurologic signs originally noted became more marked, with extreme weakness of the right arm. A positive Hoffmann sign appeared on the right, but the Babinski signs were negative. Dullness and bronchial breath sounds reappeared over the left upper lobe and were accompanied by scattered fine rales and a cough, which was moderately productive of purulent sputum. Another chest film revealed no change in the left upper lobe, but the right lung field showed increased linear markings. Pleural fluid was present bilaterally. Several convulsions of the Jacksonian type occurred, each lasting several minutes. The convulsive movements started in the right hand and arm, spreading to the leg and face. The seizures were followed by drowsiness and sleep. On the fortieth hospital day a Babinski sign was elicited on the right and there was prolonged ankle clonus on the right. There was dullness to pinprick in the right leg. On the same day the patient had a convulsion followed by temporary aphasia.

She continued to cough and raise large quantities of green mucoid sputum. She became unco-operative, refusing all food and medication. The chest signs continued unchanged. She became extremely weak and drowsy and expired on the fifty-third hospital day following a convulsive episode.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR LINENTHAL: The problem in this patient appears to be one of disease involving structures within the chest as well as the central nervous

system. Consideration of the neurologic lesion may appropriately follow discussion of the chest difficulty, since I think that the two are interrelated.

The presenting symptoms of this patient were difficulty in swallowing, difficulty in breathing, a sense of oppression in the chest, a sense of obstruction in the throat, and weakness and hoarseness of the voice. The complete paralysis of the left vocal cord, fixed in the cadaveric position midway between phonation and quiet inspiration, and the ill-defined x-ray shadow in the left hilar region suggest that these findings as well as the symptoms may have been due to some process in the left hilar region involving the left recurrent laryngeal nerve and pressing on the esophagus and trachea. The emaciated condition of the patient on admission is consistent with the impression that a malignant neoplasm was the likeliest basis of such a process.

Regarding the primary site of such a tumor, bronchiogenic carcinoma seems most probable, although other locations must be considered. It is interesting that there had been no cough and no sputum before the patient entered the hospital, but this does not rule out a pulmonary neoplasm.

The statement that a gastric ulcer had been seen by fluoroscopy raises the question whether there was a gastric neoplasm with metastases to the hilar nodes and surrounding structures. Since the abdominal symptoms that led to the fluoroscopy subsided, x-ray studies of the stomach were not repeated, and we have no evidence on which to settle this question.

There is no evidence for other diseases that might have given rise to the presenting symptoms and physical findings. Neither physical examination nor x-ray examination showed evidence of an aortic aneurysm, and examination of the larynx did not reveal any intrinsic disease. Esophageal carcinoma might well have explained the presenting picture, but since no studies of the esophagus were made, there is no way to confirm this diagnosis.

At the end of the third week in the hospital, the patient developed a pulmonary infection in the left upper lobe. This was marked by fever, cough, sputum and pain over the left chest. The respirations were rapid and shallow, and she became cyanotic. Physical examination gave evidence of consolidation over the left upper lobe, and this was confirmed by x-ray. Elevation of the white-cell count suggests a bacterial etiology, but the sputum showed only alpha-hemolytic and a few beta-hemolytic streptococci. She was given sulfadiazine and then penicillin, but there is no evidence that these were of value. The patient improved, the physical findings over the left upper lobe diminished but never entirely disappeared, and the x-ray picture showed little change.

It is interesting that this severe pulmonary infection developed in the left upper lobe, since the

lesion that I have supposed to exist at the left hilus could easily have compressed the left upper lobe bronchus and caused some increased susceptibility to infection in that area. The linear shadows seen in the third and fourth left interspaces on the first chest film may have represented small areas of atelectasis.

At the time of the development of the pulmonary infection, before the patient had received any chemotherapy, the liver was found to be enlarged. Subsequently she was given sulfadiazine, and while receiving the drug, she became jaundiced and had bile in the urine. The sulfadiazine was stopped and soon afterward, along with improvement in the pulmonary condition, the jaundice disappeared and the liver became smaller.

It is difficult to be sure of the relation between the pulmonary infection, the sulfonamide therapy and what appears to have been an episode of acute hepatitis. Toxic hepatitis has been described after sulfadiazine, but the presence of the hepatic enlargement in this case before sulfadiazine was given makes me believe that the sulfa drug was probably not responsible. Bacterial pneumonia may be accompanied by jaundice. There is also the possibility that both the pulmonary infection and the hepatitis were due to a virus infection. The negative cephalin flocculation test done at about the time the jaundice was subsiding suggests that the degree of liver damage was slight. No other liver function tests were done. The plasma proteins showed no significant change.

Obstructing lesions of the biliary tract must be mentioned, but there is nothing to support such a diagnosis and the transient hepatic enlargement is suggestive of intrahepatic disease. There was apparently no abdominal pain at that time, and there is no evidence for gallstones. Metastatic disease of the liver or around the bile passages seems too remote to be seriously considered.

The pulmonary infection never entirely cleared up, and indeed at the time of death there was an increase in the physical findings, as well as a persistence of the x-ray abnormalities over the left upper lobe and the development of purulent sputum. Apparently the infection was a persistent one, either because of some blockage of drainage from the involved lobe or because of the characteristics of the infectious process. This may well have been a virus disease with superimposed bacterial infection.

The acuteness of the onset of the pulmonary infection, together with the absence of clinical or x-ray evidence of pulmonary tuberculosis on admission, seems to eliminate tuberculosis as a possibility. Unfortunately there is no record of a search for tubercle bacilli in the sputum.

The neurologic disorder was, I think, related to the disease in the chest; that is, it was caused by a metastasis of the malignant process. The problem

here is to decide on the basis of the evidence presented how many neurologic lesions were present and where they were located.

The terminal neurologic findings were marked. The weakness in the arm, the appearance of a Hoffmann sign, the development of Jacksonian convulsions starting in the right arm and hand, the appearance of a Babinski sign on the right with ankle clonus, the increase in the deep tendon reflexes on the right and the episode of temporary aphasia point to a lesion in the left cerebral hemisphere involving primarily the motor area for the arm with extension to the motor area for the leg and to the nearby speech area. Sensory changes, such as the late dullness to pinprick in the right leg, suggest subcortical extension of the process.

The earliest manifestation of any neurologic disorder was the development of weakness in the right arm. Subsequently the muscles of the right arm and the right shoulder girdle showed atrophy. This finding suggests a metastatic lesion involving the anterior-horn cells of the right side of the mid-cervical spinal cord. There was hypotonicity, but the deep tendon reflexes were also increased. The atrophy can be explained on the basis of weakness of the right arm with resulting disuse. The stiffness in both legs at the onset is difficult to explain. The positive Romberg sign and the evidence of incoordination on admission may be attributed to weakness. It seems, therefore, that all the findings can be explained on the basis of one metastatic cerebral lesion.

The patient went down hill rapidly and died following a convulsive seizure, probably owing to involvement of a vital nervous center.

CLINICAL DIAGNOSES

Tumor involving left motor cortex of brain
(? primary, ? metastatic from bronchiogenic carcinoma).

Unresolved pneumonia: left upper lobe.

DR. LINENTHAL'S DIAGNOSES

Bronchiogenic carcinoma of left lung, with metastases to regional nodes and left cortical and subcortical regions of brain.

Unresolved pneumonia: left upper lobe.

Acute hepatitis, subsiding.

ANATOMICAL DIAGNOSES

Carcinoma, oat-cell type, of left upper lobe, with metastases to bronchial, mediastinal, mesenteric and retroperitoneal lymph nodes, liver, kidney and brain.

Chronic pneumonitis: left upper lobe.

Bronchiectasis: left lower lobe.

Cerebral pressure cones.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: As Dr. Linenthal predicted, the pulmonary and cerebral lesions were related. This woman did have a bronchiogenic carcinoma, the primary focus being in the bronchus to the left upper lobe, which was completely occluded. The metastatic bronchial and mediastinal lymph nodes had infiltrated the wall of the left main bronchus, especially the lower lobe bronchus. The latter was so narrowed that secondary bronchiectasis had developed throughout the lower lobe, the bronchioles being dilated and filled with purulent material. The primary tumor in the left upper lobe had extended into the parenchyma around the bronchus for about 4 cm., and the remaining pulmonary tissue in this lobe was gray and rubbery, characteristic of the so-called "drowned out" or "stasis" pneumonitis.

There were three cerebral metastases. The largest, and the one that caused most of the cerebral symptoms, was a cystic lesion measuring 6 by 3 by 2.5 cm. in the left parietal region. The other two, each about 2 cm. in diameter, were solid nodules, one in the right posterior frontal region and one in the posteroinferior portion of the right cerebellar hemisphere. There was definite evidence of increased intracranial pressure, as shown by flattening of the convolutions and the deep cerebellar and temporal pressure cones.

The liver weighed over 2000 gm. and contained many metastatic nodules. I do not believe, however, that there was sufficient replacement of parenchyma to have produced even the transient jaundice. A likelier explanation is the presence of many metastatic lymph nodes surrounding and compressing the common bile duct.

Microscopically the carcinoma was extremely undifferentiated, showing no tendency to either keratinization or gland formation. In many places it suggested the oat-cell type.

NOT SO GOOD

Two federal agencies that seem to have had some difficulty in retaining the confidence of the public, and between which close harmony is essential although its existence is not always apparent, are the War Food Administration and the Office of Price Administration. A duty of the WFA, through its carefully organized system of food experts, is to know month by month, as well as year by year, the food resources of the country and their proper allocation to the armed services, to lend-lease and to the civilian population. A function of the OPA is to effect and maintain a system of food rationing that will provide an equitable distribution of the country's resources so far as native intelligence and human honesty can assure it.

An example of the failure of these two agencies to co-ordinate their activities was furnished last fall when the WFA made public announcement that twelve pounds of butter per capita per year was available to the entire civil population. At that time butter was worth twenty red points per pound on the rationing list, and since each individual had available thirty points for each four-week period, no slide-rule expert was needed to apprise the concerned housewife of the fact that in order to obtain her promised butter she must give up two thirds of the points that also had to cover her expenditures for meat, cheese and other fats. As of Christmas night, moreover, the Magi whose guiding star shines over the Potomac presented a somewhat suspicious public with an increase in the point value of butter to twenty-four, and canceled many outstanding points that the thriftier housewives had been saving against a rainy day.

Thus are prudence and patriotism rewarded, and thus is the bewildered citizen encouraged to disregard the rules, since they have been changed in the middle of the game. As the *Boston Herald* notes in the leading editorial of December 27, 1944: "A government that repudiates its currency forfeits the confidence of its people. We can ill afford to lose faith in the Office of Price Administration, but its action in canceling certain unspent red, blue and sugar stamps is unpleasantly akin to currency repudiation."

It is not implied that butter is an essential kind of food; we can do without butter, as many of us have already learned. What we cannot dispense with is confidence in the agencies that are attempting to lead us through our wilderness. Probably the worst that can be said is that, like some of our military leaders, they simply did not know what was going on. In that lack of knowledge, however, they have lost face with the public to which they are eventually answerable. This has made it more difficult, moreover, for some of the volunteer citizen aides, such as the members of medical advisory committees, to solve their own problems conscientiously and to retain to any great degree the confidence of their own "public."

This country can double and triple and quadruple the sacrifices that it is making, and may yet have

to do so now that its introductory years to total war are over. It can do so with calm confidence, however, only if it can have faith in the judgment and ability of its leaders, as well as in their integrity: and this last is not being questioned. If democracy at war may be considered as passing through a forest of disillusionment guided only by a flickering lamp of patriotism, then let us at least turn our ingenuity to trimming the lamp and not to extinguishing it.

EARLY DIAGNOSIS OF TYPHUS FEVER

THE medical profession and the lay public of New England are not particularly concerned with typhus fever. This disease is a clinical curiosity in most parts of this country, particularly in New England. In many other parts of the world, however, it is of frequent occurrence and is always a serious problem. Members of our armed forces are now to be found in almost all the countries in which this or similar rickettsial diseases are both endemic and epidemic. The present war has stimulated considerable interest and activity in this field, and great strides forward have been taken in the recognition and prevention of many of the rickettsial diseases. Among the Russian investigators who have made notable contributions is Professor A. A. Smorodintsev, chief of the Virus Disease Division of the All Union Institute of Experimental Medicine in Moscow, who visited this country last year.

One of the most significant aspects of any program of prevention or eradication of an infectious disease is its early recognition. The diagnosis of typhus fever in the past has depended on the Weil-Felix reaction. This is a test for agglutinins against certain strains of the proteus bacillus in the serum of the patient. It depends on the empirical observation that such antibodies appear during the latter part of the illness, and during convalescence, of certain rickettsial diseases, including typhus fever. It is, therefore, not a highly specific reaction. Furthermore, positive results are not obtained until after the fifth day and usually only after the first week.

Smorodintsev and Drobyshvskaya¹ have recently described a complement-fixation test that is designed to detect the presence of antigen in the

serum of patients during the earliest stages of the disease. This test, therefore, has the advantage of giving the earliest possible diagnosis and probably is also more specific. It involves the use of suitably chosen convalescent serums from recovered patients, but serums from hyperimmune rabbits will presumably prove equally satisfactory or even better. The test is carried out by mixing immune serum with inactivated serum from the patient in the presence of suitable amounts of complement, and then testing for the fixation of complement with a suitable hemolytic system.

With this test, a positive diagnosis was made in all patients from whom serum was obtained during the first two days of the disease and in about 60 per cent of those from whom the serum was obtained between the third and sixth days of the disease. Positive Weil-Felix reactions did not occur in any of the serums obtained during the first four days of the disease, and this test was positive in only 38 per cent of the serums obtained on the fifth and sixth days. Moreover, between the fifth and eighth days of the disease, positive tests were obtained in one third of the serums only by the complement-fixation test and in another third only with the Weil-Felix reaction, the remaining serums being either positive or negative to both tests.

It is thus seen that in the first days of the disease this complement-fixation test is almost completely reliable, while during the latter part of the first week of the disease and possibly during the early part of the second week, the use of both the complement-fixation and Weil-Felix tests should give a positive diagnosis in at least two thirds of the cases. Although the principle involved in this method — namely, the detection of a circulating antigen early in the course of the disease — is not new, it has never before been applied in exactly this manner. It has been used to detect the type-specific soluble substance of the pneumococcus in the blood of patients early in pneumonia.² It has also been used to detect precipitinogen in early cases of yellow fever.³

Recent attempts to devise a diagnostic method more useful than the Weil-Felix reaction have resulted in a technic employing a rickettsial antigen prepared from agar tissue cultures in

a complement-fixation test,⁴ but it is obvious that such a procedure measures *antibody* rather than *antigen* in the patient's serum and that it is less likely to give a positive reaction early in the course of disease than is a test for antigen.

Since much of the work on typhus fever that has been done by workers in this country and in Great Britain is confidential and has not been published, it is more than likely that extensive observations have already been made with respect to the application of this test and possibly of others that are equally useful. The results of these and other observations will determine whether the test suggested by the Russian workers is a valuable clinical aid, and further study may reveal other virus or rickettsial diseases to which this principle may be adaptable for early diagnosis.

MISCELLANY

HOSPITALS APPROVED FOR GRADUATE TRAINING IN SURGERY

The American College of Surgeons has recently announced that two hundred and thirty-one hospitals in the United States and Canada have been approved for graduate training in general surgery and the surgical specialties. In announcing the list, Dr. Malcolm T. MacEachern, associate director, states that surveys of five hundred or more hospitals offering opportunities for graduate training in surgery are planned during the coming year, the increased emphasis on this work being stimulated by the need for providing ample opportunities for resumption of training by medical officers when they return from service with the armed forces. The College helps hospitals to organize graduate training programs to meet the requirements for approval, and also plans to aid physicians returning from service in resuming their training in surgery. The list of hospitals in Massachusetts is as follows:

HOSPITAL	APPROVED TYPE OF TRAINING
<i>Boston</i>	
Beth Israel Hospital (215 beds)	General surgery Urology
Boston City Hospital (2378 beds)	General surgery Neurological surgery Orthopedic surgery Urology
Boston Lying-in Hospital (138 beds)	Obstetrics
Carney Hospital (234 beds)	General surgery Obstetrics and gynecology
Children's Hospital (256 beds)	General surgery Neurological surgery Orthopedic surgery Otolaryngology
Lahey Clinic (New England Baptist Hospital—228 beds) (New England Deaconess Hospital—310 beds)	General surgery Neurological surgery Orthopedic surgery Urology Otolaryngology
Massachusetts Eye and Ear Infirmary (227 beds)	Ophthalmology Otolaryngology
Massachusetts General Hospital (851 beds)	General surgery Neurological surgery Orthopedic surgery Urology
Massachusetts Memorial Hospitals (414 beds)	General surgery Obstetrics
Peter Bent Brigham Hospital (108 beds)	General surgery Urology
<i>Brookline</i>	
Free Hospital for Women (101 beds)	Gynecology
<i>Worcester</i>	
Memorial Hospital (185 beds)	Otolaryngology

CORRESPONDENCE

SIGNED EDITORIALS

To the Editor: Having read the original editorial "Pharmacy and Anesthesia" with at least marked disagreement to many of the statements in it and certainly with curiosity as to who propounded them I am prompted again to suggest the wisdom of having editorials signed.

I know that this matter has already been once disposed of in opposition and with disapproval of this procedure, but I wish again to call attention to the fact that it would have so placed the responsibility for statements which are so contrary to the opinions of experienced anesthetists that I am certain that the author would have either hesitated to make them or have prepared himself more fully to support them.

It is still my conviction that the signed editorial bears greater weight and causes less confusion and even less harm than the unsigned one, which permits statements that would frequently not be made were it necessary for the author to sign his name to it.

BOOK REVIEWS

Homicide Investigation: Practical information for coroners, police officers and other investigators. By LeMoyne Snyder, M.D. With chapters by Captain Harold Mulbar, Charles M. Wilson and C. W. Muehlberger. 8°, cloth, 287 pp., with 116 illustrations. Springfield, Illinois: Charles C Thomas, 1944. \$5.00.

The purpose of this book in the words of its author is "to make available to coroners, police officers or others, whose duty it is to inquire into the nature of a homicide, tested practical plans of procedure to follow in adequately investigating the death." He refers to it as a synopsis of factual information intended to be of practical use to men without scientific training whose duties call them to investigate potentially violent deaths.

The book is well illustrated and written in simple language. It is particularly valuable in that it teaches what not to do as well as what to do. It covers the needs of the coroner or medical examiner who is isolated from larger centers, and also the progressive police chief. It includes a consideration of the value of methods of lie detection, based on the use of the Keeler polygraph, which is looked on as a valuable aid to crime detection. The work can be highly recommended as a practical guide for those for whom it is intended.

Practical Malaria Control: A handbook for field workers. By Carl E. M. Gunther, M.D., B.S., D.T.M. (Sydney). With a foreword by Prof. Harvey Sutton, O.B.E., M.D., F.R.A.C.P., B.Sc., D.P.H., F.R.San.I. 12°, cloth, 91 pp. New York: Philosophical Library, 1944. \$2.50.

The foreword by Prof. Harvey Sutton states that the author of this book, Dr. Carl E. M. Gunther, spent many years at Bulolo in the Mandated Territory of New Guinea as a field medical officer of a gold-dredging company. The seat of operations was in the midst of tropical forests where malignant tertian malaria was highly endemic. Dr. Gunther is an entomologist of repute, and a student of clinical and preventive medicine who is well acquainted with its literature; at present he is with the Australian Medical Corps.

The author offers the booklet in the hope that it may help those who are meeting malaria in the field with only an academic knowledge of the disease. Although adapted to local conditions in New Guinea, the author believes that his methods of dealing with malaria are applicable in other undeveloped districts where the population is widely scattered. The opinions expressed are based on experience gained during a period of ten years. The author recognizes that some of his views are radical, unscientific or dogmatically expressed. Dogmatism is justifiable, however, in so condensed an outline of the broad subject of malaria.

The reviewer finds that some of the author's statements regarding the absorption of quinine are of doubtful validity and that the author is in error when he says that quinine is directly toxic to all types of malaria parasites at all stages (evidently, Dr. Gunther forgot to take the sporozoite into consideration). The paucity of exact knowledge regarding the absorption and the action of quinine and other drugs in malaria, however, justifies differences of opinion.

The text contains many interesting observations. Practical methods of treatment are described in detail. The booklet should be of interest to students and of great value to medical field workers.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Practical Malaria Control: A handbook for field workers. By Carl E. M. Gunther, M.D., B.S., D.T.M. (Sydney), field medical officer, Bulolo Gold Dredging Limited, Territory of New Guinea. With a foreword by Prof. Harvey Sutton O.B.E., M.D., F.R.A.C.P., B.Sc., D.P.H., F.R. San. I. 12°, cloth, 91 pp. New York: Philosophical Library, 1944. \$2.50.

Radiation and Climatic Therapy of Chronic Pulmonary Diseases: With special reference to natural and artificial heliotherapy, x-ray therapy and climatic therapy of chronic pulmonary diseases and all forms of tuberculosis. Edited by Edgar Mayer, M.D., assistant professor of clinical medicine, Cornell University Medical College, New York City, attending physician,

New York and Memorial hospitals, special pulmonary consultant, New York State Department of Labor, and director (*ex urbe*) Northwoods and Will Rogers Tuberculosis sanatoriums, Saranac Lake, New York. 8°, cloth, 393 pp., with 46 illustrations. Baltimore: Williams & Wilkins Company, 1944. \$5.00.

This composite work of twenty-two authors reflects the present-day knowledge of the special treatment of chronic pulmonary diseases, including all forms of tuberculosis. Incorporated in the work are the clinical experiences of the editor and of many of the collaborators.

Technique in Trauma: Planned timing in the treatment of wounds, including burns. By Fraser B. Gurd, M.D., C.M., and F. Douglas Ackman, M.D., C.M., in collaboration with John W. Gerrie, M.D., C.M., Edward S. Mills, M.D., C.M., Joseph E. Pritchard, M.D., and Frederick Smith, M.D. with a preface by John S. Lockwood, M.D., University of Pennsylvania, and a commentary by Ralph R. Fitzgerald, M.D., C.M. McGill University. 4°, cloth, 68 pp., with 3 plates, 17 figures, 5 tables and 3 charts. Philadelphia: J. B. Lippincott Company, 1944. \$2.00.

This small monograph is composed of three articles that appeared in the *Annals of Surgery* in 1942, 1943 and 1944, with some additions to the text. The basis of the monograph is carried on at the Montreal General Hospital. The authors emphasize not only the importance of adherence to the basic physiologic principles, but also bring out the fact that these principles can only be applied to a large hospital by the use of sound planning and thorough teamwork.

Industrial Ophthalmology. By Hedwig S. Kuhn, M.D. 8°, cloth, 294 pp., with 114 illustrations, including 2 color plates. St. Louis: C. V. Mosby Company, 1944. \$6.50.

In this book the author attempts to co-ordinate much of the essential information relating to the various ophthalmologic problems that confront industry.

Minor Surgery. Edited by Humphry Rolleston and Alan Moncrieff. 8°, cloth, 174 pp., with 30 illustrations. New York: Philosophical Library, 1944. \$5.00.

This new manual in minor surgery is made up of eighteen articles on selected subjects, written by English authorities in their special fields. Although there is not any preface or foreword, it seems evident that this small work is published at this time for war reasons. The editing is well done and the various articles are short, emphasizing diagnosis and emergency treatment. The subjects covered include minor wounds, sprains, the foot and hand, the mouth, nose, throat and eye, bursas and ganglia, certain benign tumors and cysts, skin infections, the rectum, the genitourinary system, nonoperative treatment of hernias and the fitting of trusses and belts, varicose veins, ulcers and phlebitis, gynecology, the surgery of children, and anesthesia in minor surgery.

Virus Diseases in Man, Animal and Plant: A survey and reports covering the major research work done during the last decade. By Gustav Seiffert. 8°, cloth, 352 pp. New York: Philosophical Library, 1944. \$5.00.

In this small volume the author attempts to give a survey of the present status of virus investigations with special consideration of the most recent literature, especially that from foreign countries. The work discusses the important virus diseases of man, animal and plant, and its aim is to furnish an introduction to the study of the viruses.

Homicide Investigation: Practical information for coroners, police officers and other investigators. By LeMoyne Snyder, M.D., medicolegal director, Michigan State Police. With chapters by Captain Harold Mulbar, chief of the Identification Bureau, Michigan State Police, Charles M. Wilson, director, Chicago Police Scientific Crime Detection Laboratory, and C. W. Muehlberger, director, Michigan Crime Detection Laboratory. 8°, cloth, 287 pp., with 116 illustrations. Springfield, Illinois: Charles C Thomas, 1944. \$5.00.

a complement-fixation test,⁴ but it is obvious that such a procedure measures *antibody* rather than *antigen* in the patient's serum and that it is less likely to give a positive reaction early in the course of disease than is a test for antigen.

Since much of the work on typhus fever that has been done by workers in this country and in Great Britain is confidential and has not been published, it is more than likely that extensive observations have already been made with respect to the application of this test and possibly of others that are equally useful. The results of these and other observations will determine whether the test suggested by the Russian workers is a valuable clinical aid, and further study may reveal other virus or rickettsial diseases to which this principle may be adaptable for early diagnosis.

MISCELLANY

HOSPITALS APPROVED FOR GRADUATE TRAINING IN SURGERY

The American College of Surgeons has recently announced that two hundred and thirty-one hospitals in the United States and Canada have been approved for graduate training in general surgery and the surgical specialties. In announcing the list, Dr. Malcolm T. MacEachern, associate director, states that surveys of five hundred or more hospitals offering opportunities for graduate training in surgery are planned during the coming year, the increased emphasis on this work being stimulated by the need for providing ample opportunities for resumption of training by medical officers when they return from service with the armed forces. The College helps hospitals to organize graduate training programs to meet the requirements for approval, and also plans to aid physicians returning from service in resuming their training in surgery. The list of hospitals in Massachusetts is as follows:

HOSPITAL	APPROVED TYPE OF TRAINING
<i>Boston</i>	
Beth Israel Hospital (215 beds)	General surgery Urology
Boston City Hospital (2378 beds)	General surgery Neurological surgery Orthopedic surgery Urology
Boston Lying-in Hospital (138 beds)	Obstetrics
Carney Hospital (234 beds)	General surgery Obstetrics and gynecology
Children's Hospital (256 beds)	General surgery Neurological surgery Orthopedic surgery Otolaryngology
Lahey Clinic (New England Baptist Hospital—228 beds) (New England Deaconess Hospital—310 beds)	General surgery Neurological surgery Orthopedic surgery Urology Otolaryngology
Massachusetts Eye and Ear Infirmary (227 beds)	Ophthalmology Otolaryngology
Massachusetts General Hospital (851 beds)	General surgery Neurological surgery Orthopedic surgery Urology
Massachusetts Memorial Hospitals (414 beds)	General surgery Obstetrics
Peter Bent Brigham Hospital (108 beds)	General surgery Urology
<i>Brookline</i>	
Free Hospital for Women (101 beds)	Gynecology
<i>Worcester</i>	
Memorial Hospital (185 beds)	Otolaryngology

CORRESPONDENCE

SIGNED EDITORIALS

To the Editor: Having read the original editorial "Pharmacology and Anesthesia" with at least marked disagreement to many of the statements in it and certainly with curiosity as to who propounded them I am prompted again to suggest the wisdom of having editorials signed.

I know that this matter has already been once disposed of in opposition and with disapproval of this procedure, but I wish again to call attention to the fact that it would have so placed the responsibility for statements which are so contrary to the opinions of experienced anesthetists that I am certain that the author would have either hesitated to make them or have prepared himself more fully to support them.

It is still my conviction that the signed editorial bears greater weight and causes less confusion and even less harm than the unsigned one, which permits statements that would frequently not be made were it necessary for the author to sign his name to it.

BOOK REVIEWS

Homicide Investigation: Practical information for coroners, police officers and other investigators. By LeMoyn Snyder, M.D. With chapters by Captain Harold Mulbar, Charles M. Wilson and C. W. Muehlberger. 8°, cloth, 287 pp., with 116 illustrations. Springfield, Illinois: Charles C Thomas, 1944. \$5.00.

The purpose of this book in the words of its author is "to make available to coroners, police officers or others, whose duty it is to inquire into the nature of a homicide, tested practical plans of procedure to follow in adequately investigating the death." He refers to it as a synopsis of factual information intended to be of practical use to men without scientific training whose duties call them to investigate potentially violent deaths.

The committee recommends a plan for the sound development of physical medicine on a lasting basis. Various subcommittees have considered the subjects of teaching, basic research, clinical research, public relations, rehabilitation, hydrology and health reports, occupational therapy and body mechanics. These subcommittees presented special reports to the central committee, and that committee has recommended an immediate program and also an eventual program. The immediate program includes the organization of the central office with a governing board and an advisory board of experts in physical medicine and related medical fields, the establishment of fellowships and residencies in physical medicine, the promotion of teaching of and research in physical medicine in all approved medical schools, the promotion of wartime and postwar rehabilitation and the provision for preparation and publication of reports of the committee. The eventual program has to do with the promotion and advancement of physical medicine through various public channels, including the adoption of certain resolutions concerning projects of organizations on which the committee looks with favor. The reports of the subcommittees are printed in full.

Tropical Nursing; A handbook for nurses and others going abroad. By A. L. Gregg, M.D., M.Ch., B.A.O. (Dublin), D.T.M. and H. (Lond.), L.M. (Rotunda Hosp.), member of associate staff and lecturer to nurses, Hospital for Tropical Diseases, London, and lecturer on tropical diseases, Westminster Hospital Medical School. Second edition. 16°, cloth. 185 pp. New York: Philosophical Library, 1944. \$3.00.

This small book has been written primarily for nurses in the field. There is a short chapter on personal hygiene in the tropics, followed by consideration of nursing in the various tropical diseases. There is also a chapter on the technics and special methods used in treatment. The last chapter is on the care of the eyes.

The Treatment of Peptic Ulcer. By George J. Heuer, M.D., professor of surgery, Cornell University Medical College and surgeon-in-chief, New York Hospital. Assisted by Cranston Holman, M.D., assistant professor of clinical surgery, Cornell University Medical College; and William A. Cooper, M.D., assistant professor of clinical surgery, Cornell University Medical College. 8°, cloth, 118 pp., with 2 charts. Philadelphia: J. B. Lippincott Company, 1944. \$3.00.

This monograph is based on the case histories of 1204 patients with gastric, duodenal or marginal ulcers admitted to the New York Hospital for various reasons. The book is divided into two parts — medical treatment and surgical treatment. There is also a chapter on the incidence of malignant neoplasms, and another gives a survey of pertinent literature, with an appended bibliography.

Synopsis of Neuropsychiatry. By Lowell S. Selling, M.D., Ph.D., D.P.H., director, Psychopathic Clinic, Recorder's Court, Detroit, Michigan, associate attending neuropsychiatrist, Eloise Hospital, and adjunct attending neuropsychiatrist, Harper Hospital, Detroit. 12°, cloth, 500 pp. St. Louis: The C. V. Mosby Company, 1944. \$5.00.

This simplified manual has been written for the student with the hope that it will serve him as a quick guide for diagnosis and treatment and provide a background for intensive review.

Psychiatry and the War: A survey of the significance of psychiatry and its relation to disturbances in human behavior to help provide for the present war effort and for postwar needs. Edited by Frank J. Sladen, M.D., physician-in-chief, Henry Ford Hospital, Detroit. 8°, cloth, 505 pp. Springfield, Illinois: Charles C Thomas, 1943. \$5.00.

This book is made up of a collection of papers presented to a conference on psychiatry at the University of Michigan. It is a survey of psychiatry and its closely allied fields. The work is divided into five parts: the philosophy of psychiatry; research in psychiatry; psychiatry in the training, experience and education of the individual; psychiatry and the war; and review of the subjects already presented, which were summarized in two symposiums.

Infections of the Peritoneum. By Bernard Steinberg, M.D., director, Toledo Hospital Institute of Medical Research. With a foreword by Frederick A. Collier, M.D., professor of

surgery, University of Michigan Medical School, and director, Department of Surgery, University Hospital, Ann Arbor, Michigan. 8°, cloth, 455 pp., with 45 illustrations and 21 tables. New York: Paul B. Hoeber, Incorporated, 1944. \$8.00.

This new work on peritonitis embodies the experience of the author during the last eighteen years. The work is designed for the practitioner who is confronted with the task of arriving at a diagnosis and mapping out the therapy. Most of the book is devoted to the clinical aspects of infections of the peritoneum, and many new views in the developmental mechanisms, etiology, diagnosis and treatment of peritoneal infections are included.

Bacterial Infection: With special reference to dental practice. By J. L. T. Appleton, D.D.S., Sc.D., professor of bacteriology and dean, Thomas W. Evans Museum and Dental Institute School of Dentistry, University of Pennsylvania. Third edition, thoroughly revised. 8°, cloth, 498 pp., with 86 engravings and 5 plates. Philadelphia: Lea and Febiger, 1944. \$7.00.

The primary purpose of this book is to aid the reader in forming a comprehensive concept of infection. The work is written primarily for dentists, and this third edition has been thoroughly revised and rearranged. New chapters on the ecology of the micro-organisms of the mouth, actinomycosis and osteomyelitis have been added. The work is divided into three parts: morphology, physiology and ecology of bacteria; infection; and special infections of the oral cavity.

Principles and Practices of Inhalational Therapy. By Alvan L. Barach, M.D., associate professor of clinical medicine, Columbia University College of Physicians and Surgeons, and assistant attending physician, Presbyterian Hospital, New York City. 8°, cloth, 315 pp., with 59 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$4.00.

This new monograph is written for physicians who wish to understand the physiologic basis, as well as the technics, of inhalation therapy. The book opens with a short chapter on the historical and physiologic background, followed by a discussion of all the diseases in which the therapeutic use of gases is indicated; it concludes with methods and apparatus used in the treatment.

Physical Medicine in General Practice. By William Bierman, M.D., attending physical therapist, Mount Sinai Hospital, New York City, and assistant clinical professor of therapeutics, New York University Medical College. 8°, cloth, 654 pp., with 310 illustrations and frontispiece. New York: Paul B. Hoeber, Incorporated, 1944. \$7.50.

This new textbook has been written for the practitioner in general and special fields of medicine. The work is condensed, covering all the agencies used in physical therapy and their applications to diseases of the various systems of the body. Historical references, as a rule, have been omitted, as well as extensive descriptions of the physics of light, heat and electricity.

One Hundred and Fifty Years Service to American Health. By Schieffelin and Company. 8°, cloth, 73 pp., with 30 illustrations and frontispiece. New York: Schieffelin and Company, 1944.

This small volume relates the interesting history of the oldest drug house in America, first founded in 1781 and still in active business in New York City, with a continuous history of one hundred and sixty-three years. The book is well done and contains a number of interesting illustrations. It is worthy of a place in all medical history collections.

A Dynamic Era of Court Psychiatry, 1914-1944. Edited by Agnes A. Sharp, M.A., Ph.D. 8°, paper, 149 pp., with illustrations. Chicago: The Psychiatric Institute of the Municipal Court of Chicago, 1944.

The Psychiatric Institute of the Municipal Court of Chicago was established on May 1, 1914. This small volume consists of a number of articles by the staff of the institute on the various aspects of the work of the department. The book has two functions: to record the history of the first thirty years of the institute, and to present scientific facts of court psychiatry.

The War and Mental Health in England. By James M. MacKintosh, M.D., professor of preventive medicine, University of Glasgow. 8°, cloth, 91 pp. New York: The Commonwealth Fund, 1944. 85 cents.

This collection of nine informal essays discusses in non-technical language mental health in England during the first four years of the present war, with the outlook for the remainder of the war and the postwar period. The author considers the impact of the war on the new soldier, the industrial worker, the hospital patient and the civilian. In discussing the efforts that are being made to safeguard mental health in England the author considers such topics as hospital service and rehabilitation, and professional education. Dr. MacKintosh has long been connected with the mental-hygiene movement in Great Britain, and in these essays he gives a picture of wartime conditions in England.

Stop Worrying and Get Well. By Edward Podolsky, M.D. 8°, cloth, 124 pp. New York City: Bernard Ackerman, Incorporated, 1944. \$2.00.

In this small book the author attempts to show how to meet daily problems in a sound way, without putting an undue strain on the mind and the nervous system. The author in a popular way discusses the effects of the mind on the body in health and disease.

Hydronephrosis and Pyelitis (Pyelonephritis) of Pregnancy: Etiology and pathogenesis (a historical review). By H. E. Robertson, M.D., Section on Pathologic Anatomy, Mayo Clinic, Rochester, Minnesota. 8°, cloth, 332 pp., with 11 illustrations. Philadelphia and London: W. B. Saunders Company, 1944. \$4.50.

In this historical survey the author has endeavored to present a fairly complete account of all the important work that has been done on dilatation and infection of the ureters in pregnancy. A comprehensive bibliography of 974 references is appended to the text, and all these articles are referred to throughout the work. This small book should prove a valuable reference source to all physicians interested in obstetrics and genitourinary diseases and to all libraries.

Poliomyelitis. By Edward C. Rosenow, M.D. Vol. A 44 of the International Bulletin for Medical Research and Public Hygiene (Editor-in-chief, W. L. Colze). 8°, paper, 87 pp., with 26 illustrations and 16 tables. New York: The International Bulletin, 1944. \$2.75.

In this pamphlet Dr. Rosenow summarizes his work on the streptococcal causation of poliomyelitis and the streptococcal source of the virus causing the disease. Dr. Rosenow states that he has succeeded in inoculating *Macacus rhesus* monkeys with his poliomyelitis virus, producing the clinical and pathologic picture of the disease, and completing twenty-seven years' work on the relation of streptococci to epidemic poliomyelitis and its virus. A summary is also given regarding treatment of the disease with antistreptococcus serum, showing that the death rate is greatly lower in patients treated with the serum. A bibliography of 115 references is appended to the text.

Elimination Diets and the Patient's Allergies: A handbook of allergy. By Albert H. Rowe, M.D., lecturer in medicine, University of California Medical School, San Francisco, California, and consultant in allergic diseases, Alameda County Hospital, Oakland, California. Second edition, thoroughly revised. 8°, cloth, 256 pp. Philadelphia: Lea and Febiger, 1944. \$3.50.

This new edition has been thoroughly revised, and the entire text reset. The cereal-free elimination diet has been adjusted because of the scarcity of some foods. Indications for the use of fruit-free elimination diet are discussed for the first time. A new special elimination diet for the control of colitis and various supplemental diets for unusual types of food allergy, as well as special diets for obesity and diabetes and for infants and children, are given in detail. All menus

and recipes have been revised in the light of rationing and restriction of foods owing to the present war.

Small Community Hospitals. By Henry J. Southmayd, director, Division of Rural Hospitals, the Commonwealth Fund; and Geddes Smith, associate, The Commonwealth Fund. 8°, cloth, 182 pp. New York: The Commonwealth Fund, 1944. \$2.00.

This small book outlines the experience of the Commonwealth Fund during the past twenty years in the organization, construction and operation of small community hospitals in various parts of the United States. Persons interested in small hospitals in any of their aspects will find here a frank discussion of all the major questions facing such hospitals. The text lays stress on hospital administration rather than on the hospital plant. However, there is a chapter on building design, covering the broad architectural principles that have been tested in fourteen community hospitals. From an executive point of view the relations of the board of directors, the medical staff, the superintendent and the staff are discussed in sufficient detail to give the beginner a practical understanding of hospital management. In 1925, the Commonwealth Fund embarked on a definite program for the building and operation of small fifty-bed community hospitals, servicing an area of approximately twenty-five to thirty-five square miles. The fund proposed to meet two thirds of the cost of building and equipment, and the communities were to provide suitable sites, responsible management and the necessary maintenance cost. It is thus seen that aid was offered only to communities that would assume a stated share of the capital costs and would guarantee the necessary funds for maintenance and in due time become independent of foundation subsidy or supervision. Under this plan twelve hospitals have been completed, together with a county hospital built before the plan was formerly launched and an older hospital remodeled and reorganized in co-operation with the fund. The hospitals were also required to subscribe to the minimum standard for hospitals of the American College of Surgeons. This small work is aimed directly at the nonprofessional men and women who take the responsibility for the community hospital. It is written in nontechnical language and should be in every small public library in the country.

The Principles and Practice of Ophthalmic Surgery. By Edmund B. Spaeth, M.D., professor of ophthalmology, Graduate School of Medicine, University of Pennsylvania, attending surgeon, Wills Hospital, Philadelphia, consultant in ophthalmology, Philadelphia Hospital for the Insane, Byberry, and assistant ophthalmologist, Rush Hospital, Philadelphia. Third edition, thoroughly revised. 8°, cloth, 934 pp., with 556 engravings, containing 798 figures and 6 colored plates. Philadelphia: Lea and Febiger, 1944. \$11.00.

This third edition of a standard work has been revised by the addition of much new material and many new illustrations, thus bringing the contents fully up to date. In view of the unusual demand made on ophthalmologists by the war, emphasis has been placed on traumatic conditions. The section on muscles now includes a discussion on the physiology of squint, and the section on ptosis and its etiologic factors has been almost completely rewritten.

A National Health Service. By the Ministry of Health for Scotland. Reprinted. 8°, paper, 85 pp. New York: Macmillan Company, 1944. 75 cents.

This pamphlet describes and discusses the proposed comprehensive health service for England, Scotland and Wales. This plan will be put into effect on the termination of the war, and the purpose of this pamphlet is to examine the subject generally, showing what is meant by a comprehensive service and how it fits with what has been done in the past and what is being done in the present. The topics discussed include general administration, hospital and consultant service, general-practitioner service, clinic and other services, payment for the service and the application of the plan to Scotland.

Report of the Baruch Committee on Physical Medicine. For the Committee, by Ray Lyman Wilbur, M.D., chairman. 8°, paper, 120 pp. New York: Baruch Committee on Physical Medicine, 1944.

THE MECHANISM OF RENAL COMPLICATIONS IN SULFONAMIDE THERAPY

EDWIN L. PRIEN, M.D.*

BROOKLINE, MASSACHUSETTS

THE ever-increasing number of case reports of renal complications in sulfonamide drug therapy indicates that neither the mechanism of their production nor the means of preventing them is yet understood. The following observations are offered in the hope that they may contribute to a better comprehension of this problem.

Early experience with sulfapyridine and sulfathiazole showed that it was mainly the insoluble acetyl derivatives of the drugs that crystallized in the urinary passages, producing obstruction and anuria. It was immediately obvious that a large urinary output would tend to keep these derivatives in solution and to prevent this complication. When sulfadiazine became available, it was predicted that the greatly increased solubility of acetylsulfadiazine in urine would be an important factor in such prevention,¹ but numerous reports in the literature show that this drug is by no means harmless in respect to the formation of crystals.

Various observers have described these crystalline sulfonamide deposits in the bladders, ureters, kidney pelves and tubules of patients who died of sulfonamide anuria, or who recovered when obstruction was relieved by ureteral catheterization. Similar lesions have been produced experimentally in animals by the use of large doses of the drugs.²⁻⁴ When the crystalline deposits were not found in the ureters or kidney pelves at autopsy, it was assumed that they had been washed from the urinary tract before death. Gritty deposits noted on the cut surfaces—presumably within the tubules—of the kidneys of patients dying in anuria could usually not be demonstrated in microscopic sections because they had been dissolved from the tissues by the water and reagents used in preparing the sections. The finding of clefts suggesting that crystals had previously been present strengthened this belief. Subsequently various workers were able to prepare sections that demonstrated the obstructing concretions in situ in the renal tubules. It was believed that in all cases the kidney complications were due to such deposits.

*Associate urologist, Newton Hospital; assistant urologist, Boston Lylogio Hospital.

So far as can be determined, Long, Haviland, Edwards and Bliss⁵ were the first to state that anuria in sulfonamide therapy may also be due to a true toxic injury of the kidney tubules similar to that seen in mercury bichloride poisoning. This was confirmed by Prien and Frondel,⁶ who failed to find crystals in frozen sections of patients dying of sulfathiazole anuria. The histologic changes noted in these unobstructed kidneys were degeneration and focal necrosis of tubule cells and interstitial edema. Lederer and Rosenblatt⁷ and Merkel and Crawford⁸ described areas of focal necrosis in the kidneys and other organs and failed to find bacteria in these lesions; the changes in the kidneys included evidence of concretions and extensive tubular damage. Lyons⁹ states that two types of renal complications occur—one a toxic effect on the tubules and the other a result of the precipitation of crystals. Sobin, Aronberg and Rolnick¹⁰ have found focal necroses in human material that presented the clinical syndrome of sulfathiazole toxicity. Their conclusion that it has not been demonstrated that the renal changes in sulfonamide toxicity are independent of tubular obstruction by crystals seems justified.

NONOBSTRUCTIVE SULFONAMIDE ANURIA

The two following case reports are offered as evidence that uremia and anuria may occur without obstruction of the renal tubules or urinary channels by concretions and are presumably due to a true toxic injury of the kidney tubules.†

CASE 1.† A 39-year-old man developed pneumonia and was given 10 gm. of sulfathiazole in 24 hours. The temperature fell on the day after starting chemotherapy, and he became drowsy and perspired profusely. He failed to urinate on the 2nd day after the drug was started. He was catheterized, and the 480 cc. of concentrated urine obtained showed a large trace of albumin but no crystals. For the next 4 days the patient was intermittently comatose and responsive. The temperature was normal, and the pulmonic condition showed

†I am indebted to Dr. Mooroe J. Schlesinger, pathologist of the Beth Israel Hospital, who studied the biopsied tissue of these cases critically and provided fresh autopsy tissue for studies of frozen sections.

‡I am indebted to Dr. George C. Prather and Dr. Ralph Volk for permission to study and report this case.

Sexual Anomalies and Perversions: Physical and psychological development and treatment. By Magnus Hirschfeld, M.D., president of the World League for Sexual Reform, and director of the Institute for Sexual Research, Berlin. 8°, cloth, 630 pp. New York City: Emerson Books, Incorporated, 1944. \$4.95.

This volume comprises a summary of the works of the late Dr. Hirschfeld and is compiled as a memorial by his pupils. The book was originally published in England, and the sheets have been imported and bound in the United States to supply the American professional public. The present work was originally planned by Dr. Hirschfeld as a textbook for those who need knowledge of sexual pathology. He died before he completed his work, and his pupils finished the book and prepared it for the press. The book is divided into five parts: The physical basis of sexuality; irregular sexual development and quantitative irregularities; deflections of the sexual impulse; sexual aberrations arising from fixations on component impulses; and other partial impulses. Because of its character the volume is restricted to the medical and legal professions, to ministers and to educators and special students in the fields of psychology, biology and sociology.

Female Endocrinology, Including Sections on the Male. By Jacob Hoffman, M.D., demonstrator in gynecology, Jefferson Medical College, and pathologist in gynecology, Jefferson Hospital. 8°, cloth, 780 pp., with 180 illustrations. Philadelphia: W. B. Saunders Company, 1944. \$10.00.

This new treatise is divided into three parts: physiology of the endocrine glands; the clinical aspects of gonadal and reproductive endocrinology; and laboratory work. In presenting the clinical material, emphasis is placed on disturbances of functional organs. Diagnostic aids adapted for use in endocrine disorders are described. The hormonal preparations now available for the treatment of gonadal and reproductive disorders are described and tabulated, and their indications and contraindications are fully considered. Select bibliographies are attached to each chapter, and appended to the text is an index of names for all articles mentioned in the book.

Clinics. Vol. II: No. 5. (February 1944). Edited by George Morris Piersol, M.D., professor of medicine, Graduate School of Medicine, and professor of clinical medicine, School of Medicine, University of Pennsylvania, Philadelphia. 8°, paper, 266 pp., illustrated. Philadelphia: J. B. Lippincott Company, 1944. \$2.00.

Simplified Diabetic Management. By Joseph T. Beardwood, Jr., M.D., associate professor of medicine, Graduate School of Medicine, University of Pennsylvania, physician to the Presbyterian Hospital, Philadelphia, physician-in-chief to the Department of Metabolic Diseases, Abington Memorial Hospital, Abington, Pennsylvania, visiting physician in charge of diseases of metabolism, Bryn Mawr Hospital, Bryn Mawr, Pennsylvania, and chief of the Metabolic Department, Philadelphia Hospital for Contagious Diseases; and Herbert T. Kelly, M.D., associate in medicine, Graduate School of Medicine, University of Pennsylvania, associate physician, Presbyterian Hospital, Philadelphia, and chief, Department of Medicine, Doctors' Hospital, New York City. Fourth edition. 12°, cloth, 172 pp., with 7 illustrations and charts. Philadelphia: J. B. Lippincott Company, 1944. \$1.50.

This manual has been revised and brought up to date in relation to present-day conditions. Diabetic diets have been revised to conform to war and food-rationing regulations. Many of the chapters have been simplified, especially that on acidosis. There has been included a new chapter, which discusses the care of the diabetic woman during pregnancy. The manual is primarily for the diabetic patient to serve as a guide and daily source of reference.

Manual of Urology. By R. M. LeComte, M.D., professor of urology, Georgetown University School of Medicine. Third edition. 8°, cloth, 305 pp., with 60 illustrations. Baltimore: The Williams and Wilkins Company, 1944. \$4.00.

The third edition of this students' manual has been carefully revised and brought up to date. Emphasis has been placed on traumatic lesions, which have increased as a result

of mechanized warfare. A chapter on pain has been included, and the section on neurogenic bladder disorders has been rewritten and simplified.

The Medical Clinics of North America. New York Number (May, 1944). *Psychosomatic Medicine.* 8°, cloth, 262 pp., illustrated. Philadelphia and London: W. B. Saunders Company, 1944. \$3.00.

The Medical Clinics of North America. Mayo Clinic Number (July, 1944). *Chemotherapy.* 8°, cloth, 239 pp., illustrated. Philadelphia and London: W. B. Saunders Company, 1944. \$3.00.

NOTICES

BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held in the Main Lecture Room of the Harvard Biological Laboratories on Wednesday, January 17, at 8 p. m.

PROGRAM

Transient Block of Conduction in Nerve Fibers Produced by Pressure or Ischemia. Dr. D. E. Denny-Brown.

Histochemical Reactions Associated with Basophilia and Eosinophilia in the Human Placenta. Drs. E. W. Dempsey and G. B. Wislocki.

The Argentaffin Cells of the Gastric Mucosa of Mammals. Dr. A. B. Dawson.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held at the Beth Israel Hospital on Tuesday, January 23, at 8:15 p. m. Dr. Paul Klemperer, of the Mount Sinai Hospital, New York City, will read a paper "Disseminated Lupus Erythematosus and Allied Conditions." Discussion by Dr. Monroe Schlesinger, Benjamin Castleman and M. Edward MacMahon will follow.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, January 16, at twelve noon. The meeting will be devoted to a nutritional film in technicolor, which will tell of the detection and treatment of nutritional diseases. This will be discussed by Drs. Tom Spies and Norman Jolliffe and others. Physicians are cordially invited to attend.

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

The annual meeting of the New England Ophthalmological Society will be held at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, on Tuesday, January 16, at 8 p. m.

Following the business meeting, which will include the election of officers, Dr. Edwin B. Dunphy will speak on the subject "Experiences in England." This will be followed by a paper "The Inheritance of Ocular Abnormalities" by Dr. R. Ruggles Gates, emeritus professor at the University of London.

NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting of the New England Roentgen Ray Society will be held at the Harvard Club, Boston, on Friday, January 19. There will be an x-ray conference at 4:30 p. m. At 8:00 p. m., a symposium on the topic "Osteomyelitis" will be presented; Dr. Edward B. D. Neuhauser will discuss "Roentgenologic Diagnosis" and Dr. Chester S. Keefer, "Methods of Treatment."

(Notices continued on page xv)

lymphocytes and plasma cells in the focal areas. The tubules were not dilated, nor was there evidence of crystalline material or pus. A diagnosis of focal tubular necrosis of the kidney was made.

It is well recognized that renal decapsulation for the relief of anuria fails in the great majority of cases, regardless of the cause of the condition. The polyuria after operation in this case, however, was too dramatic to be explained on the basis of gradual improvement characteristic of a healing process. The apparent success of decapsulation does not constitute an unqualified endorsement for its universal use in sulfonamide anuria.

The kidney tissues removed by biopsy and the fresh kidney tissue obtained post mortem in Case I were examined for crystals in the tubules. Frozen sections were cut and the sections removed directly from the microtome knife to a glass slide without preliminary floating of the cut section in water. Some difficulty was encountered in transferring frozen sections directly to glass slides without crumpling of the tissue. By freezing the microtome knife and the glass slide just before each cut was made, presentable sections were obtained. A drop of mineral oil — in which the sulfonamides are insoluble — and a coverslip were placed over the section, which was then examined with a polarizing microscope. Tissue detail was readily observed. No crystals were present in any of the sections. The frozen sections were correlated with formalin-fixed paraffin sections. This technic had previously been successfully used to demonstrate sulfonamide crystals in kidney tubules.¹⁴ By the use of this method no crystals are lost from the tissues by solution because no solvents are used at any time.

The possibility that, in Case I, crystals disappeared from the tissues after death and before frozen-section examination is also ruled out. By prior arrangement the kidneys were not washed or sponged at the autopsy table until blocks of fresh tissue had been taken for frozen sections. Furthermore, careful search of the urinary tract, from the renal papillas to the bladder, failed to reveal any crystals or concretions. In two other cases of sulfathiazole anuria with similar careful post-mortem examination, no crystals were found anywhere in the urinary tract. This is supported by the failure to find crystals in the urine of nonfatal cases of sulfathiazole oliguria.^{6, 12, 13}

It may be argued that the crystals were washed out by the urine after they caused the kidney damage and that the changes in the kidneys were not due to the drug. A number of relevant observations have been made.

Gross, Cooper and Lewis^{2, 14} fed large amounts of sulfapyridine to rats for several weeks and noted the results. When the rats were killed at the end of the feeding period, they showed calculi in the urinary tract in a preponderance of cases; when the animals were allowed to live for ten days after ad-

ministration of the drug was stopped, no calculi could be found, but there was dilatation of the tubules and other presumptive evidence that calculi had been present for a time. Presumably — it is so implied — it takes some time for calculi to be washed from the urinary tract after they are formed. What is most important, however, in so far as it bears on acute toxicity, is that calculi were found in the urinary tracts in *all* the rats that died during the period of drug administration.

A most instructive observation has been made by Lehr, Antopol and Churg.¹⁵ They injected mice intraperitoneally with massive single doses of sulfathiazole and noted the location of its precipitation in the urinary tract. Depending on the time interval between injection and death of the animal, the precipitate was found in different parts of the tract. If death occurred within a few hours after the injection, the collecting tubules and papillary ducts were filled with a whitish material that extended into the pelves, ureters and bladder. After twenty-four hours the precipitate in the kidneys disappeared and the bladder became filled with white crystalline material that consisted almost entirely of free sulfathiazole. If the animals survived for at least several hours, anatomic signs of irritation were found in the kidneys — marked enlargement with congestion and edema. It appears that because of the extremely acute nature of the experiment these animals were able to flush their kidneys free of crystals before toxic damage to the renal epithelium produced oliguria, with resulting stagnation of crystals in the tubules.

If the findings of Gross, Cooper and Lewis are applied to the 2 clinical cases reported, it appears that both patients should have recovered spontaneously because their urinary tracts were found to be free of obstructing concretions when examined. Either obstructing crystals were never present or they were washed out before cystoscopy and biopsy were done. There is no reason to assume that the latter condition existed. After the onset of symptoms of uremia there was marked oliguria, and no crystalline precipitate was noted in the urine either before or after entry to the hospital.

If it is assumed that the areas of focal necrosis in the kidneys represent the damage done by transitory concretions, it is only logical to expect such damage to have been more pronounced in the collecting tubules²⁻⁴ and, in the autopsy case, in the tubules of the renal papilla. The literature²⁻⁴ records that in kidneys that contain crystalline deposits there is usually microscopic evidence of extensive tubular damage. But the tubular epithelium was intact in these locations except for the scattered foci that occurred throughout the entire kidney. The distribution of these foci did not correspond at all to the generally recognized localization of the tubular concretions. The objection that cortical biopsies do not give information on concretions located in the

evidence of resolution. He received 2000 cc. of 10 per cent dextrose solution intravenously each day, but remained anuric except for 240 cc. of urine obtained by catheter on the 9th day after starting the drug. He was admitted to the Beth Israel Hospital the next day. He had passed a rigid life-insurance examination less than a year before.

In the hospital the patient was semicomatose, but could be aroused. Examination of the chest showed evidence of a clearing pneumonic process, which was confirmed by x-ray examination. The blood pressure was 124/75. There was tenderness to palpation over the right upper quadrant but none over the costovertebral angles. There was moderate edema of the lower back and lower extremities.

Of the three catheterized urinalyses recorded, the reaction was alkaline in two, and acid in the third. The specific gravity varied from 1.016 to 1.018, and the albumin from none to a heavy trace. There was no sugar. The sediment showed a few coarsely granular and hyaline casts, 10 to 30 leukocytes and none to 12 red cells per high-power field and many bacteria but no crystals. The blood counts were normal except for leukocytosis. The blood nonprotein nitrogen was 167 mg. per 100 cc.

On the 2nd hospital day, the nonprotein nitrogen rose to 190 mg. and the blood pressure to 190/130. The carbon dioxide combining power of the blood was 38 vols. per cent, and the blood chloride 440 mg. per 100 cc. *Staphylococcus aureus* was cultured from the urine. The patient received almost constant intravenous infusions of dextrose and normal saline solution up to 5300 cc. daily, but remained anuric except for small amounts of urine obtained by catheterization.

Late on the 2nd day, cystoscopy and retrograde pyelography were done. No concretions were seen in the bladder, and no obstruction was encountered by the urethral catheters. The kidney pelves and ureters were poorly outlined in the pyelograms. It was thought that the kidney tubules were blocked by crystals, because no obstruction was demonstrated in the kidney pelves and ureters, and a rapid bilateral renal decapsulation was done under spinal anesthesia. Considerable edema was encountered in the flank muscles. The kidneys were enlarged, but the capsules were not so tense as had been expected. Tissue was taken by biopsy from the cortex of each kidney. There was no postoperative improvement, and the patient died the following day.

Microscopic examination of the biopsy specimens showed the glomeruli to be normal. The convoluted and collecting tubules were not remarkable except for small scattered focal areas of necrosis. These were represented by desquamation and breaking up of the lining epithelium of small groups of tubules, and by infiltration of a few polymorphonuclear leukocytes into these tubules. A diagnosis was made of multiple focal necroses of the kidney tubules.

Autopsy. The right kidney weighed 295 gm., and the left 285 gm. Both kidneys were much swollen. The remnant of the capsule stripped readily. The external surfaces were normal. The cut surface showed irregular grayish areas suggesting degeneration. The cortices measured 0.6 to 1.0 cm. in width and were sharply demarcated from the medullas. They showed similar but more marked degeneration. The calyces, pelves and ureters were normal. No crystals or concretions were present.

Microscopic examination of the kidneys showed the glomeruli to be normal except for congestion in certain areas. The capsular spaces were empty. For the most part the convoluted and collecting tubules appeared normal. Widely scattered throughout the cortex and medulla were small groups of tubules that showed cloudy swelling and desquamation. In a few places the lumens of the convoluted and collecting tubules were irregularly filled with necrotic cellular debris and granular, hyaline and cellular casts. The interstitial tissue was not increased in amount and was infiltrated, sometimes densely, with lymphocytes and plasma cells adjacent to the degenerating tubules. An occasional polymorphonuclear leukocyte was seen. In the cortex these focal areas usually appeared to be adjacent to glomeruli. The focal tubular degeneration was less marked than in the biopsy sections taken 2 days before death, which suggested that the lesions had begun to heal.

The anatomic diagnoses were as follows: bronchopneumonia of the left upper lobe; acute bronchitis; bilateral renal decapsulation; kidney biopsy wounds; arteriosclerosis of spleen; subacute passive congestion of liver; chronic duodenitis; congestion of the jejunum, ileum and stomach; subacute

diffuse pancreatitis; focal necrosis of the adrenal glands; focal tubular degeneration of the kidneys; glandular hyperplasia of the prostate gland; congestion of the bladder; and hemorrhagic urethritis.

The second case is particularly interesting because it showed a pathologic process in the kidneys similar to that of the first case and because of the dramatic improvement following renal decapsulation.

CASE 2.* A 47-year-old housewife developed a temperature of 104°F. and was found to have an injected throat. Her physician gave her 20 gm. of sulfathiazole in 3 days. Her temperature was normal on the 4th day and she got out of bed. Six days later there was a recurrence of fever with sore throat. The patient received 32 gm. of sulfathiazole in 5 days. Antral puncture was done on the 6th day, and a small amount of pus was obtained. She voided little urine on this day and only 30 cc. in the next 24 hours. She was admitted to the Beth Israel Hospital.

The only significant findings on physical examination were an injected pharynx and tenderness on pressure over both kidneys, both anteriorly and posteriorly. The blood pressure was 140/80, temperature 100°F., the pulse 90, and the respirations 20.

Catheterized urines were uniformly alkaline before operation except for one specimen, which was acid; the albumin before operation varied from none to a trace. After operation the urine never showed more than a very slight trace of albumin and contained none 2 weeks later. There was no sugar. The urinary sediment before operation showed none to 20 leukocytes per high-power field but no drug crystals. The blood was normal except for a hemoglobin of 80 per cent (Sahli).

At entry the blood nonprotein nitrogen was 70 mg. per 100 cc., the carbon dioxide combining power 37 vols. per cent, the chloride 390 mg. per 100 cc., and the sulfathiazole 2.3 mg. The nonprotein nitrogen rose to 100 mg. on the next day and remained above normal until 13 days after operation. The carbon dioxide combining power remained below 40 vols. per cent until 5 days after operation. A blood culture was sterile, and urine cultures were reported as positive for *Staph. albus*.

On the 2nd hospital day, the patient received 4000 cc. of 5 per cent dextrose and of normal saline solution intravenously; the urinary output was only 45 cc. On the 3rd day, she received 50 per cent dextrose and normal saline solution, the total volume being 2200 cc., and began to show signs of peripheral and pulmonary edema. The urinary output was 15 cc. Cystoscopy was done on the 4th day and showed nothing abnormal. Both ureters were catheterized with ease, and small amounts of urine were obtained. This was followed by decapsulation of the left kidney under cyclopropane anesthesia. A biopsy from the left kidney cortex was taken at operation. The kidney was somewhat swollen, but did not bulge after decapsulation.

The effect of renal decapsulation on the fluid balance was immediate and remarkable. On a fluid intake of 2200 to 4000 cc. daily for 3 days prior to operation, the urinary output was only 45 cc. 2 days before operation and only 15 cc. on the day before it. On the 1st postoperative day it was 410 cc., and on the next day it rose to 1200 cc., climbing to a peak of 6100 cc. 8 days after operation. The intake after operation varied between 1600 and 3400 cc., with a daily average of 2500 cc.

The temperature on the day of operation reached 101°F. and thereafter fell slowly by lysis to normal. A mild pneumonic process appeared 5 days postoperatively but was of no contributory significance. An intravenous pyelogram on the 20th postoperative day showed good excretion by both kidneys within 5 minutes of injection of the dye—a normal response.

The pathological report on the tissue removed at biopsy was similar to that in Case 1. The glomeruli and most of the tubules were normal. The degenerative process in the involved tubules was slightly more diffuse and appeared to be in a later, almost healed stage. The epithelium of the tubules appeared quite intact, and there was evidence of regeneration of tubule cells. The interstitial tissue showed infiltration of

*I am indebted to Dr. George Gilbert Smith for permission to study and report this case.

ner, the filling process progressing up the collecting tubules toward the convoluted tubules. Careful study of frozen sections in 5 cases has failed to show crystals in the collecting tubules (or higher) unless the terminal portions of these tubules were also filled with crystals. It is not necessary to assume that the pelvis or calyces must be completely filled with crystals before the tubular deposition and obstruction can occur. Such has not been found to be the case. The building up of the delta at the mouth of the Mississippi River and the progressive silting of the lower river occur despite the fact that the Gulf of Mexico has not been filled up with sediment.

The early development of this process was observed in the kidney of an elderly patient who had received sulfathiazole for a massive pneumonia.¹¹ At autopsy the calyces and pelvis of one kidney contained much crystalline material and there was a concretion blocking the ureter just above the bladder. Under the polarizing microscope acetyl-sulfathiazole crystals were found in the terminal portions of the collecting tubules, but there were no crystals higher in the collecting or convoluted tubules. No crystals were lost from the kidney tubules in preparation of the tissues because the previously described rigorous frozen-section waterless technic was followed.

The factor of crystal affinity is of great importance in the production of obstruction of the urinary tract. This is a surface-tension phenomenon. Crystals of the acetyl derivatives of the sulfonamides — and crystals in general — have an affinity for one another; and this causes them to adhere together to form aggregations or concretions. Anyone who has gently agitated a heavy suspension of crystals on a glass slide under the microscope and allowed the preparation to stand for a time has noted the familiar clumping of crystals.

The deposition of crystals in stagnant urine permits them to come in contact with each other to form concretions by simple aggregation. This may occur in the tubule, calyx or pelvis. Such masses of crystals then behave as ordinary urinary calculi, lodging in the kidney pelvis or the lower ureter or passing to the bladder when size permits. The readiness with which concretions form undoubtedly bears a relation to the number of crystals in the urine. The larger the volume of urine the less opportunity there is for the random collision and aggregation of crystals in suspension. If crystals are kept far apart, there is less tendency for concretions to form.

Prien and Frondel⁶ examined the crystals in a series of 310 specimens of urine from patients receiving sulfathiazole therapeutically, and failed to find any correlation between the number of crystals in the urinary sediments and the presence or absence of evidence of renal irritation — oliguria, hematuria or albuminuria. The urines of certain

patients suffering renal toxicity showed no crystals. On the other hand, the urines of most patients with extremely heavy crystalline deposits showed no evidence of renal complication. These urines had stood at room temperature for some hours, and the crystals did not appear until the urines had cooled to room temperature.

Crystalluria, as determined by the observation of ordinary cooled urines, is probably without significance unless there is oliguria, hematuria or other evidence of renal irritation. But, as Janeway²⁴ has pointed out, the presence of numerous crystals in freshly voided urine still at body temperature is extremely significant. The urinary concentration of the drug must be rapidly decreased by forcing fluids and either reducing or withholding the drug until the crystals disappear. Further therapy must be carried on with extreme caution.

The role of urinary stasis in the causation of concretions has been shown. Crystallization is favored in stagnant water. Residual bladder urine should be eliminated, whether due to cystocele, obstruction by the prostate or urethral stricture. Bedridden patients receiving large doses of the sulfonamides should be placed on urethral catheter drainage if the residual urine exceeds 60 cc.

SUMMARY AND CONCLUSIONS

Renal complications to sulfonamide therapy continue to occur despite an increasing experience and the use of the more soluble sulfonamide drugs. The usual mechanism that produces these complications is the obstruction of the urinary channels by insoluble concretions composed principally of the acetyl derivatives of the drugs. Less frequently, a toxic injury of the tubules, independent of concretions, produces anuria and uremia. In such cases the only lesion in the urinary tract may be a widely disseminated focal necrosis of the kidney tubules.

Two cases of sulfathiazole anuria and uremia are reported. No obstructing concretions were encountered in the ureters or kidney pelves by cystoscopy and pyelography. Renal decapsulation was done and cortical biopsies taken. One patient died. The other recovered rapidly, apparently as a result of decapsulation. There were no crystals or concretions in the kidney tissue taken by biopsy or in the entire urinary tract (including the kidney tubules) of the fatal case that came to autopsy. A rigorous technic is described that precludes the loss of drug crystals in preparation of tissues.

The most important factor in causation of renal complications is a low urinary output.

The development of obstructing concretions depends on two physical conditions — the hydrodynamics of the urinary tract and the affinity of crystals for each other.

Crystals of the sulfonamides first form in the convoluted tubules, where reabsorption of water occurs. Sedimentation of these suspended crystals

medulla may be answered inferentially. Lack of evidence of tubular obstruction or damage of the collecting tubules in the cortex and the ready correlation of the biopsy and autopsy sections to show a consistent picture of a single lesion (focal necrosis) afford evidence that concretions were not present in the tubules of the renal pyramids.

It has been shown by numerous observers that uremic death may occur from tubular obstruction by acetylsulfathiazole concretions. It is agreed that temporary arrest of concretions in the urinary channels may produce kidney embarrassment and that such deposits may be washed out or dissolved if insufficient to produce uremic death in human beings before this clearing process is completed. But that extensive deposition of impacted crystals extending through the renal pyramids with accompanying anuria for several days will be relieved spontaneously seems doubtful.

If, in the 2 clinical cases, crystals had been present for a time only and had disappeared before the tissues were taken for study, some clinical improvement should have been manifested if the anuria was on a simple mechanical basis. It is a commonplace observation that temporary obstruction, as by a ureteral calculus, produces little kidney damage if there is no infection. The ability of the kidneys to clear themselves of crystals would be evidence of returning or surviving renal function. But in these cases the uremia became more profound with the lapse of time. It is possible that the persisting anuria was due to epithelial damage. In the absence of clinical or pathological evidence of concretions, it is reasonable to assume a primary chemotoxic cause for the focal lesions in the kidneys.

It may be objected that the changes in these kidneys were of a nonspecific nature and, together with the uremia, can be explained on the basis of toxicity due to the disease under treatment. This is unlikely. The picture is that of a transient focal degenerative process widely disseminated through the renal tubules and tending to heal without gross scar. Staphylococci were present in the urines of both patients, yet the lesions in the kidneys were not typical of such infection, nor did they suggest any other clinical condition. Furthermore, the uremia immediately followed the use of the drug. It has been produced experimentally in healthy animals by feeding sulfathiazole.

Dr. Schlesinger made an interesting observation concerning sequential relations in the biopsy and autopsy specimens. In Case 1 there appeared to be a definite progression in the degenerative and healing process, as evidenced by the sections taken at biopsy and at autopsy, two days intervening. The biopsy in Case 2 illustrates a later stage in the same healing process. The first patient received his initial dose of the drug nine days before the kidney was biopsied; the second patient received her first dose seventeen days before biopsy, or eight days

earlier. In other words, the second patient's lesion appeared to show a healing stage eight days farther along than that of the first patient. No conclusions are drawn from this observation; it is merely offered as an interesting commentary.

OBSTRUCTIVE SULFONAMIDE ANURIA

Although it is impossible to enlarge much on the causation of nonobstructive sulfonamide anuria beyond stating that it is probably due to a primary chemotoxic cause, much more can be said about the mechanism of the obstructive type of anuria. Prerenal factors, such as concentration of the drug in the bloodstream and excessive acetylation,¹⁶⁻¹⁷ will not be discussed.

It is probable that crystals first form in the convoluted tubules of the kidney following concentration of urine by reabsorption of water. When deposits of insoluble acetyl derivatives are present, it is reasonable to assume that a supersaturated solution existed in situ or farther up the urinary tract. Scrutiny of the literature shows that there is no essential difference between sulfapyridine, sulfathiazole and sulfadiazine in the localization of the concretions.^{2, 3, 12, 18-23} Furthermore, the presence of a single crystal is enough to "seed" a supersaturated solution and initiate mass crystallization. This happens in motionless solutions and is probably not strictly applicable to the urinary tract unless there is marked stasis.

The development of obstructing sulfonamide concretions from crystals in the kidneys is probably dependent on two physical conditions, the hydrodynamics of the urinary tract and the affinity of crystals for each other. The renal tubule empties its contents into the calyx in a manner analogous to the discharge of a slow-flowing river into a lake or other large body of still water. The discharge of the Mississippi River into the Gulf of Mexico provides a good analogy. Because of the disappearance of the current of the river at its mouth, suspended particles of mud and so forth are dropped, to form the well-known delta in the Gulf of Mexico. This formation builds up to such a height that the water flowing over it becomes very shallow and the fall or grade of the river becomes low. As a result, the current is slowed and deposition of suspended material occurs in the lower reaches of the river. Certain measures, such as dredging, are necessary to prevent the river from filling up and overflowing its banks.

In a similar manner the flow of urine through the renal tubule slows where the tubule empties into the broad expanse of the calyx. Not enough current remains to carry the suspended crystals onward. They are deposited in the calyx, impeding and then obstructing the flow in the terminal portions of the collecting tubules. The resulting stasis in the tubule serves to deposit more crystals. The tubules then fill with crystals in a retrograde man-

many physicians volunteered before the Procurement and Assignment Service began to function. Some local communities have suffered through unexpected deaths. The Procurement and Assignment Service has undertaken to furnish replacements wherever possible, and several thousand have been accomplished so far. Between 50,000 and 60,000 out of an estimated 140,000 active physicians in the country are enrolled in the armed services today.

But this does not tell the whole story. There were 3156 deaths among physicians in 1943. About 6000 medical students will graduate this year with the accelerated program, but the great majority will go immediately into service, leaving only the physically unfit and a few women physicians for civilian practice. These will not be enough to replace those who die. But after this year even this number will be reduced, because the Army has cut its quota of students in medical schools from 55 to 28 per cent; the Navy quota remains at 25 per cent, leaving 47 per cent to be filled by physically disabled men and by women — an almost unattainable percentage. The Selective Service regulations refuse to allow the deferment of premedical students eighteen years of age or over and the entering classes this fall will probably be reduced 25 or 30 per cent. This is perhaps the most serious situation confronting the medical profession today. If the flow of students into the schools is not maintained, certainly not enough graduates will emerge at the other end. Much pressure has been brought to bear to change this ruling, even on the President himself, but to no avail. The Army and Navy maintain that the need of young men for combat service transcends every other requirement. A bill is now pending in Congress to amend the Selective Service Act so as to allow the deferment of premedical and medical students, but it is doubtful if it will prevail. The only hope is that the war in Europe will be over shortly, thereby lessening the need for so many medical officers and allowing at least some of the older ones to return to civilian practice. This the Army has promised to do promptly.

But the medical profession has not been allowed to determine its own policy in what is perhaps the most important thing of all — medical education. The accelerated program was practically forced on the medical schools by the military leaders. It allows no time for a breathing spell between semesters for the students to rest and assimilate what they have learned or for the overworked teachers to get their second wind. The 9-9-9 program for interns and residents, set up in the face of loud protests by the leaders in our profession, scrapped overnight the carefully worked out program of graduate training calculated to furnish adequate background for the practice of medicine and for training for the various specialties.

Only about 1000 men, representing one sixth of the graduates deferred for residencies, will have the

least possible knowledge of any specialty. Of course, postgraduate instruction must be provided for these men. What form it shall take need not concern us here. Many minds and many committees are working on the problem. But what of the 3000 graduates who get only nine months of rotating internship? These men are the great source of concern at the present moment. Deplorable as the situation is, it confronts us, particularly those in hospitals not connected with medical schools. We must exert ourselves to the utmost to give these boys all they can take in nine months.

This leads naturally to certain thoughts I have in mind concerning hospitals — those of approximately 150 beds or over not connected with medical schools in the New England cities. There are about fifty of these, representing over 12,000 beds.

It is a trite remark that a hospital is an integral part of a community, and that the community should recognize its responsibility to support it. A hospital is made up of three parts — the trustees, the administration and the medical staff. No two of these can function without the third, and there should be a most cordial and sympathetic relation between the three; there should be no pulling at cross purposes. The trustees should take the staff as much as possible into their confidence; they should seek to know the various staff members and to understand their viewpoint, which is so often different from the layman's. A definite liaison should be set up between the two bodies through an intermediary unit — an executive committee, staff council or what you will. This should consist of certain members elected by the staff — not too large to be unwieldy but large enough to be representative of the various services. The director of the hospital should be an *ex officio* member. Meetings should be frequent, with a frank exchange of ideas and opinions that will prevent many unpleasant episodes that weaken the *esprit de corps* of the hospital.

I said that a community should recognize its responsibility to the hospital. Do hospitals always recognize their responsibility to their communities? This consists primarily in furnishing the best possible medical care. The first requisite for good medical care is a well-organized medical staff. This is a requirement under the minimum standard for approval as a Class A hospital set up by the American College of Surgeons. There should be a chief of staff or a chief of each service: this also is a minimum requirement. But it should be required that the Chief be given definite authority, and that he be chosen for his leadership, enthusiasm and ability to use his authority courageously and tactfully. Seniority should never be the deciding factor in his selection.

One often hears the distinction made between a teaching and a nonteaching hospital. This is wrong. Every hospital should be a teaching hospital. Someone can always be found to teach, if there are

occurs in the terminal portions of the collecting tubules and in the renal calyx. Proximity of crystals here results in aggregation and the formation of concretions that obstruct the terminal portions of the collecting tubules. This process progresses in a retrograde manner up the collecting tubules. Calyceal concretions remain in situ or pass down the ureter much as do ordinary urinary calculi.

PRESIDENTIAL ADDRESS*

The Role of the Community Hospital in Postgraduate Teaching

WALTER G. PHIPPEN, M.D.†

SALEM, MASSACHUSETTS

THE early meetings of this society were interrupted by World War I, and now another war disrupts its schedule. At the time of the last meeting the country was not at war, but everyone thought it soon would be. Selective service was already under way, and the Procurement and Assignment Service was in its last month of gestation. It was born in October, and then out of the blue December sky came the dastardly attack on Pearl Harbor, and war.

Through that winter and summer we had to adapt ourselves to dimouts, blackouts and air-raid alarms; the rationing of food, fuel and gasoline; the depletion and rearrangement of hospital staffs; and many other discomforts that made each approaching day uncertain and unpredictable. As the fall approached it seemed wise to the Executive Committee to postpone the prearranged meeting in Worcester. The fall of 1943 was no better, — in fact, conditions were worse, — and the meeting was again postponed. This year it was decided to chance a one-day meeting, and I am sure you will feel it has been successful.

Preparation for a world war to be fought on numerous fronts required the drafting of many millions of men from all walks of life. No groups

were excluded by law except ministers of the Gospel and divinity students. The medical profession was, however, granted a privilege accorded no other group. The Procurement and Assignment Service — made up entirely of medical men, was set up by presidential decree and given quasi-official authority, at first under the Federal Security Agency and later under the War Manpower Commission. It was charged with the voluntary procurement of enough medical officers for the armed services, selected with careful thought concerning the needs of medical schools, hospitals and civilian care. The Army and Navy agreed not to commission any doctor who was not declared available for military service by the Procurement and Assignment Service. A heavy responsibility was courageously accepted by state chairmen and local committees. They have done their work well. Medical schools have been able to retain enough of their faculty members so that the teaching has not been too much curtailed. Hospitals have been able to maintain their staffs, — much depleted, to be sure, — and the quality of service has for the most part been kept fairly normal. Many retired members have gladly resumed their former positions. Many mistakes have been made. Some communities have suffered badly, particularly in the South, where

*Presented at the annual meeting of the New England Surgical Society, Boston, September 20, 1944.

†Chief of the Surgical Service, Salem Hospital.

many physicians volunteered before the Procurement and Assignment Service began to function. Some local communities have suffered through unexpected deaths. The Procurement and Assignment Service has undertaken to furnish replacements wherever possible, and several thousand have been accomplished so far. Between 50,000 and 60,000 out of an estimated 140,000 active physicians in the country are enrolled in the armed services today.

But this does not tell the whole story. There were 3156 deaths among physicians in 1943. About 6000 medical students will graduate this year with the accelerated program, but the great majority will go immediately into service, leaving only the physically unfit and a few women physicians for civilian practice. These will not be enough to replace those who die. But after this year even this number will be reduced, because the Army has cut its quota of students in medical schools from 55 to 28 per cent; the Navy quota remains at 25 per cent, leaving 47 per cent to be filled by physically disabled men and by women — an almost unattainable percentage. The Selective Service regulations refuse to allow the deferment of premedical students eighteen years of age or over and the entering classes this fall will probably be reduced 25 or 30 per cent. This is perhaps the most serious situation confronting the medical profession today. If the flow of students into the schools is not maintained, certainly not enough graduates will emerge at the other end. Much pressure has been brought to bear to change this ruling, even on the President himself, but to no avail. The Army and Navy maintain that the need of young men for combat service transcends every other requirement. A bill is now pending in Congress to amend the Selective Service Act so as to allow the deferment of premedical and medical students, but it is doubtful if it will prevail. The only hope is that the war in Europe will be over shortly, thereby lessening the need for so many medical officers and allowing at least some of the older ones to return to civilian practice. This the Army has promised to do promptly.

But the medical profession has not been allowed to determine its own policy in what is perhaps the most important thing of all — medical education. The accelerated program was practically forced on the medical schools by the military leaders. It allows no time for a breathing spell between semesters for the students to rest and assimilate what they have learned or for the overworked teachers to get their second wind. The 9-9-9 program for interns and residents, set up in the face of loud protests by the leaders in our profession, scrapped overnight the carefully worked out program of graduate training calculated to furnish adequate background for the practice of medicine and for training for the various specialties.

Only about 1000 men, representing one sixth of the graduates deferred for residencies, will have the

least possible knowledge of any specialty. Of course, postgraduate instruction must be provided for these men. What form it shall take need not concern us here. Many minds and many committees are working on the problem. But what of the 3000 graduates who get only nine months of rotating internship? These men are the great source of concern at the present moment. Deplorable as the situation is, it confronts us, particularly those in hospitals not connected with medical schools. We must exert ourselves to the utmost to give these boys all they can take in nine months.

This leads naturally to certain thoughts I have in mind concerning hospitals — those of approximately 150 beds or over not connected with medical schools in the New England cities. There are about fifty of these, representing over 12,000 beds.

It is a trite remark that a hospital is an integral part of a community, and that the community should recognize its responsibility to support it. A hospital is made up of three parts — the trustees, the administration and the medical staff. No two of these can function without the third, and there should be a most cordial and sympathetic relation between the three; there should be no pulling at cross purposes. The trustees should take the staff as much as possible into their confidence; they should seek to know the various staff members and to understand their viewpoint, which is so often different from the layman's. A definite liaison should be set up between the two bodies through an intermediary unit — an executive committee, staff council or what you will. This should consist of certain members elected by the staff — not too large to be unwieldy but large enough to be representative of the various services. The director of the hospital should be an *ex officio* member. Meetings should be frequent, with a frank exchange of ideas and opinions that will prevent many unpleasant episodes that weaken the *esprit de corps* of the hospital.

I said that a community should recognize its responsibility to the hospital. Do hospitals always recognize their responsibility to their communities? This consists primarily in furnishing the best possible medical care. The first requisite for good medical care is a well-organized medical staff. This is a requirement under the minimum standard for approval as a Class A hospital set up by the American College of Surgeons. There should be a chief of staff or a chief of each service; this also is a minimum requirement. But it should be required that the Chief be given definite authority, and that he be chosen for his leadership, enthusiasm and ability to use his authority courageously and tactfully. Seniority should never be the deciding factor in his selection.

One often hears the distinction made between a teaching and a nonteaching hospital. This is wrong. Every hospital should be a teaching hospital. Someone can always be found to teach, if there are

occurs in the terminal portions of the collecting tubules and in the renal calyx. Proximity of crystals here results in aggregation and the formation of concretions that obstruct the terminal portions of the collecting tubules. This process progresses in a retrograde manner up the collecting tubules. Calyceal concretions remain in situ or pass down the ureter much as do ordinary urinary calculi.

PRESIDENTIAL ADDRESS*

The Role of the Community Hospital in Postgraduate Teaching

WALTER G. PHIPPEN, M.D.†

SALEM, MASSACHUSETTS

THE early meetings of this society were interrupted by World War I, and now another war disrupts its schedule. At the time of the last meeting the country was not at war, but everyone thought it soon would be. Selective service was already under way, and the Procurement and Assignment Service was in its last month of gestation. It was born in October, and then out of the blue December sky came the dastardly attack on Pearl Harbor, and war.

Through that winter and summer we had to adapt ourselves to dimouts, blackouts and air-raid alarms; the rationing of food, fuel and gasoline; the depletion and rearrangement of hospital staffs; and many other discomforts that made each approaching day uncertain and unpredictable. As the fall approached it seemed wise to the Executive Committee to postpone the prearranged meeting in Worcester. The fall of 1943 was no better, — in fact, conditions were worse, — and the meeting was again postponed. This year it was decided to chance a one-day meeting, and I am sure you will feel it has been successful.

Preparation for a world war to be fought on numerous fronts required the drafting of many millions of men from all walks of life. No groups

were excluded by law except ministers of the Gospel and divinity students. The medical profession was, however, granted a privilege accorded no other group. The Procurement and Assignment Service — made up entirely of medical men, was set up by presidential decree and given quasi-official authority, at first under the Federal Security Agency and later under the War Manpower Commission. It was charged with the voluntary procurement of enough medical officers for the armed services, selected with careful thought concerning the needs of medical schools, hospitals and civilian care. The Army and Navy agreed not to commission any doctor who was not declared available for military service by the Procurement and Assignment Service. A heavy responsibility was courageously accepted by state chairmen and local committees. They have done their work well. Medical schools have been able to retain enough of their faculty members so that the teaching has not been too much curtailed. Hospitals have been able to maintain their staffs, — much depleted, to be sure, — and the quality of service has for the most part been kept fairly normal. Many retired members have gladly resumed their former positions. Many mistakes have been made. Some communities have suffered badly, particularly in the South, where

†Chief of the Surgical Service, Salem Hospital.

head, and to a lesser degree with the Cable Memorial Hospital at Ipswich.

The American Board of Surgery has set up an admirable curriculum for the training of surgeons, but the diplomats of this body will be spread out rather thin for many years to come. We of the New England Surgical Society are diplomats, but do we do all the surgery for New England? I venture to say that we do only a small fraction of it.

There are not residencies enough to accommodate all the graduates who desire to continue surgical training. Of thirty-three hospitals in New England with 200 beds or over, which might be considered large enough to furnish adequate clinical material for a resident, only nine are approved for residencies, and not all these are surgical. Most of the hospitals could provide excellent training for a resident in surgery if they would organize their staffs in some such manner as I have indicated. These hospitals represent almost 7000 beds, a fair proportion of which are assigned to surgical patients. The criticism is often raised that having a residency interferes with intern training. I do not believe that this is true. An intern should have at least eighteen months of rotating service. This will give him perhaps six months of surgery, including urology and orthopedics, but not enough to permit him to do major operating. Furthermore, the supervision and assistance a resident can give an intern is invaluable.

It is also said that a resident takes away work from the younger staff members. If the work is properly arranged this should not be so. The resident can be of great assistance with private patients, who present a field of training largely ignored in many hospitals. It is just as proper to use private patients in teaching, as it is ward patients, provided that it is done wisely. The old apprentice system certainly used private patients to good advantage. It taught the young doctor something about the art of medicine as well as about the science of medicine. How can he learn this better today than by accompanying the older surgeon on his private visits? This type of training is badly needed. So many young men know all there is to know about a given disease but nothing whatever about the personality that happens to harbor that disease.

One fault that must be overcome is the tendency for men who have been residents in hospitals in large teaching centers to feel that they must remain there indefinitely. Many must and should remain, of course — but there are certainly others who can go out into small communities to practice surgery, to their own advantage as well as that of the community. They should not do so in the expectation that they will immediately become chiefs and do

all the surgery. This thought invites disaster. They need not be ashamed to take a humble position on the staff, sell their talent to their associates, and work their way up to become leaders. Such men, if they are patient and tactful, can eventually build up a strong organization in almost any hospital. There is an immense amount of satisfaction in creative work. You who are associated with graduating residents can do much to encourage this migration.

The value of some sort of group practice has been proved beyond reasonable doubt. It is not possible to organize a private group clinic in every community; indeed, in many it may be extremely unwise. It is possible, however, to establish an informal group in many of these hospitals. If a sincere effort is made to encourage men to fill the various specialties, a reasonably complete staff can be developed. If the laboratory and x-ray setup is good and frequent consultations are encouraged, resident patients at least may have the advantage of group practice.

We should look forward to the day when all the doctors on the active staff of a hospital will have their offices in the hospital, or near enough to it for them to use its facilities easily for their ambulatory patients. This would represent a substantial economy to physicians and patients alike, in both time and money.

The need of greater supervision in surgery as well as in teaching is clear. It is so easy to master the technics of operations; it is so difficult to acquire the much more necessary surgical judgment.

You may say that I am addressing these remarks to the wrong audience. You may say that all the hospitals in which you are interested fulfill these qualifications. Be this as it may, there are many New England hospitals that are not and never have been represented in this society. Nevertheless, from time to time, either in medical meetings or in consultation service, or even in friendly association, we come in contact with some members of their staffs or boards of trustees. Should we not use such opportunities to urge the value of good staff organization? Membership in this society carries with it an implication of leadership in surgery. Twenty-seven years ago your first president, Dr. Samuel Jason Mixer, wise and sagacious leader, of whom this memorial gavel is a yearly reminder, said: "Through training of mind and hand, hospital experience under the control of able masters — these are absolute essentials and should be insisted upon in the future as they have not been in the past. It is the duty of this society to use its influence in this direction."

31 Chestnut Street

no interns — try it on the nurses. Remember teaching is like Portia's "mercy": "It is twice bless'd: It blesseth him that gives and him that takes." But teaching in a hospital requires leadership; you would not have a school without a master or a medical school without a dean. A teaching hospital will not function without a chief. Rotating services without the continuity provided by an active chief are outmoded, yet how many hospital staffs have just that, with a chief on paper?

Daily ward rounds should be regular and punctual, be conducted with decorum and be attended by all the members on service at the time. Casual rounds at all hours are demoralizing for nurses and interns alike. I know of a hospital where the visiting surgeon makes rounds whenever he chooses, and the assistant likewise. If they happen to meet, well and good; if not, assignments to operate or questions of treatment are communicated by telephone. Is it small wonder that this hospital has difficulty in getting good interns. Unfortunately, this situation can probably be duplicated many times. There should be free discussion of interesting cases at the time of the visit, not necessarily at the bedside, which may be unwise in small hospitals where gossip travels on invisible wings. The intern should be given a chance to state his views.

The minimum standard requires certain qualifications for staff membership. They are not enough. Every new member of the staff should be seen by the chief or by a staff committee and informed what his privileges as a member are at the moment and what they may be expected to be in the future. Qualifications for every step in the professional ladder should be explicitly set down in writing. It should be distinctly understood at the start that promotions are made on merit, not by seniority. If this is clearly understood when a man accepts membership on the staff and signs the bylaws, many future unpleasant episodes will be avoided. On the other hand, the younger members of the staff should not be left to their own devices, but should be encouraged to progress by special ward work, regular reading or discussions of cases.

In many hospitals, men are not restricted in their care of private patients, so that they can attempt operations or treat illnesses that they would not be allowed to do on ward service. This applies to the so-called "courtesy staff." If a man is not considered competent to undertake a ward service, he should not be allowed unrestricted privileges for his private cases. This is becoming more important with the increasing popularity of the Blue Cross and other insurance schemes, which tend to remove patients from ward service to a semiprivate status.

A well-organized staff presupposes a proper laboratory and x-ray facilities, adequate clinical records and the correct use of case-history teaching in regular clinical conferences. These conferences are of great value. If they are held at the same day and

hour each week, the habit of attendance is soon formed. If they are sporadic, the attendance will be likewise. A few full-time men, such as a pathologist, a radiologist and an anesthetist, form an excellent nucleus for such an organization. An essential part of every hospital is a good working library, with its nucleus the weekly, monthly and quarterly medical periodicals, so arranged that they can be easily consulted. The *Quarterly Cumulative Index* should occupy a prominent place. An interested staff member should be in charge as librarian, and books of reference should be carefully chosen, with due regard to the various branches of medicine. The trustees should be made to see the wisdom of setting apart adequate physical quarters for such a library, quiet and off the beaten line of travel. An intern — or a staff member, for that matter — cannot be expected to read studiously unless he is given a proper place in which to read.

It is not always realized how much this kind of setup means to a hospital. In the first place, it makes all the difference in the world in getting a quota of good interns. Even before the war there were not enough interns to go around, and naturally they chose the hospital with a reputation for good service and good training. There seems to be an underground method of communication among prospective interns. Again, the public does not realize how much this type of organization means to the community. I do not believe that the trustees realize it, or they would do more to bring it about. The more efficient hospital facilities are, the more incentive there is for young medical graduates to settle in the community. Hospital opportunities are considered a necessity today, and men look the hospital situation over carefully before deciding where to start practice. This is going to be even more so as men come back from service, having little or no idea where they want to practice.

Now all this requires tactful leadership and sympathetic co-operation; it also requires the active support of a well-informed board of trustees. Yet it is not unattainable in any of the New England hospitals.

There are small hospitals in many communities that cannot fulfill all these requirements. They cannot be expected to provide equipment for elaborate medical or surgical procedures or to furnish adequate laboratory and x-ray facilities. It is often possible for a hospital of this kind to co-operate with a neighboring, larger and better-equipped hospital, to the mutual advantage of both. Periodic laboratory and x-ray service can be furnished by the larger institution, and complicated medical or surgical cases can be transferred to it from the smaller hospital without prejudice if its staff is given appropriate appointments in the larger hospital. The Salem Hospital has an extremely satisfactory agreement of this kind with the Mary Alley Hospital of Marble-

tion of the thiochrome method of Hennessy and Cerecedo.¹¹

RESULTS

Data concerning the history of the 18 samples and the results of the assays are reported in Table 1, but in order to simplify the discussion of the results they will be considered under separate headings.

Fat

In their studies of goat's milk, Matthews and Weaver¹² found 7.79 per cent of fat and Holm and Webb¹³ 6.0 per cent. Gamble, Ellis and Besley³ conducted a three-year study of goat's milk and obtained an average of 3.50 per cent of fat, with a

extensive summary of data reported in the American and foreign literature, he cites a minimum content of 2.29 per cent and a maximum of 7.57 per cent.

In this study the fat content varied from 3.1 to 5.6 per cent and averaged 4.0 per cent. This value is closely similar to the 4.1 per cent reported by Asdell and Marquardt,¹⁸ the 4.09 per cent reported by Turner, Ragsdale and Garrison¹⁹ and the 3.50 per cent reported by Potts and Simmons.⁴

Bacteria Content

A survey of the literature revealed almost no information concerning the bacteria content of goat's milk. Gamble, Ellis and Besley³ found in 728 samples from 200 to 9800 bacteria per cubic cen-

peak of 5.00 per cent in February, from which time the fat content declined slowly but consistently until December. Lythgoe¹⁴ found that the fat content of 36 herd samples of goat's milk varied from 2.4 to 6.8 per cent, with an average of 4.45 per cent. In assays of 439 samples of individual goat's milk the range was from 1.90 to 9.80 per cent, with an average of 4.43 per cent. Lythgoe also found a peak of 5.13 per cent in February, which was followed by a seasonal decline. In a study of 18 samples of goat's milk, Peterson, Turner and Ralston¹⁵ reported a range of 2.30 to 6.50 per cent, with an average of 4.80 per cent. Besley¹ compared the composition of Holstein milk with combined Toggenburg and Saanen milk and reported 3.50 per cent for the latter. Ormiston and Gaines¹⁶ determined the fat content of milk from eight breeds of goats and found from 4.08 per cent for Toggenburg to 6.37 per cent for Anglo-Nubian, with an average of 4.76 per cent for all breeds, but Trout¹⁷ obtained less — that is, 3.54 per cent for Toggenburg, 4.41 per cent for Nubian, 4.18 per cent for Saanen and 3.84 per cent for the mixed breeds. The variation for his group of 40 samples was from 2.70 to 5.10 per cent, with an average of 3.49 per cent, but in his

timer, with an average of 775. Of these bacteria 87 per cent were *Micrococcus epidermidis*, 11 per cent were *M. aurantiacus*, and 2 per cent were *M. varians*, but none of the bacteria isolated appeared to have pathologic significance.

The bacteria count for the 18 samples of goat's milk under consideration varied from 100 to 6000 per cubic centimeter, with an average of 1300. It will be noted on reference to Table 1 that with the exception of 5 samples the bacteria count was extremely low. The average for 13 samples was 300 per cubic centimeter, a value much lower than that ordinarily obtained for cow's milk.

Hydrogen-Ion Concentration

In his study of the composition of 40 samples of goat's milk, Trout¹⁷ obtained pH values ranging from 6.33 to 6.52. Schultz and Chandler²⁰ examined 160 samples and found that the hydrogen-ion concentration varied from pH 6.4 to 6.7. The average pH for 86 morning samples was 6.52 and for 74 evening samples 6.54, with an average of 6.53 for the total number. Gamble, Ellis and Besley³ report that the pH of 4 samples of goat milk ranged from 6.54 to 6.57.

AMHERST, MASSACHUSETTS

IT HAS been estimated that the retail value of goat's milk produced in this country exceeds \$100,000,000 annually. A large portion of fluid goat's milk is used for infants, for invalids and for consumption in the home of the producer.

Various claims have been made for the superiority of goat's milk over cow's milk. Besley¹ states that of the two, goat's milk has larger amounts of albumin and nonprotein nitrogen, greater quantities of vitamin B₁, a softer curd and smaller fat globules. Richards² reports "the fact that goat's milk is alkaline in its reaction while cow's milk is acid, a matter of the greatest importance to persons suffering from hyperacidity of the stomach." According to Gamble, Ellis and Besley,³ the difference in appearance between the pigmented cow's milk fat and the colorless goat's milk fat appears to be due to a more thorough conversion of carotene to vitamin A in the latter. On the other hand, Potts and Simmons⁴ report that analyses of milk carried out at the Bureau of Animal Industry, United States Department of Agriculture, showed no significant differences in calcium, phosphorus, iron and copper content between goat's and cow's milk. Furthermore, a review of the literature revealed relatively little information concerning the vitamin content of goat's milk. Accordingly, more information concerning its quality and vitamin potency is needed for judging its value and use, and this study was undertaken to accumulate such additional data.

EXPERIMENTAL PROCEDURE

The samples of raw goat's milk used in this study were obtained from various localities within an area of about 100 miles from Amherst. Eighteen samples of milk were shipped to the laboratory by the producers in the usual containers, packed in cracked ice. The temperature of the milk on arrival was 32 to 40°F. The samples were examined for fat content and bacteria count within four hours after their arrival. Since the milk had been produced in widely scattered localities, it was impossible to make the vitamin assays immediately following milking, and since information was desired concerning the vitamin content of goat's milk that had been

handled under commercial conditions, it was decided to hold the milk in storage for the longest period that might occur under commercial conditions. Accordingly, after the raw milk arrived at the laboratory it was held in a commercial milk-refrigerating room until it was seven days old.

According to the owners the goats were either pure-bred or grade animals. Three breeds were represented, Nubian, Saanen and Toggenburg, the largest proportion of the goats being Toggenburg. They were all normal, healthy animals. Their ages varied for the different herds. The extreme ages were eighteen months and ten years, but the average age was about four years and, judging by the producers' reports, the animals were largely in the latter half of the lactation period. To secure data representative of the Massachusetts industry, samples of goat's milk were obtained from producers having different-sized herds. Furthermore, it will be noted from Table 1 that some samples were taken from a single animal and some were composites from several animals.

All the samples were obtained at the end of April from goats that had received a winter ration of hay and commercial grain mixtures for five or six months previously. None of them had been pastured or had received silage. The quality of the ration obviously varied with the different herds, for the hay was described as "poor quality," "alfalfa," "excellent," "local grown" and "mixed hay," and the commercial grain mixtures were of several brands and of different compositions. In addition, the goats that produced Sample 18 were given carrots and vegetable trimmings as a supplementary noon feeding.

The fat was determined by the Babcock method, and the bacteria count was made by the procedure outlined in *Standard Methods for the Examination of Dairy Products*.⁵ A Coleman instrument was used to determine the pH value. The ascorbic acid content of the milk was determined by the method reported by Holmes, Tripp, Woelffer and Satterfield⁶ and Tripp, Satterfield and Holmes.⁷ The niacin was assayed by the microbiologic method of Krehl, Strong and Elvehjem.⁸ The microbiologic procedure of Neal and Strong⁹ was used for assaying the pantothenic acid. The riboflavin content was determined by the method reported by Holmes, Jones, Wertz and Kuzmeski,¹⁰ except that potassium permanganate and hydrogen peroxide were used instead of stannous chloride and sodium hyposulfite for discharging any extraneous color. The thiamine content was determined by a modifica-

silage. On the other hand, Peterson, Haig and Shaw²² found no decrease in the riboflavin content of cow's milk that had been stored in a refrigerator for seven days.

Thiamine

In their comparison of goat's and cow's milk, Gamble, Ellis and Besley³ compared the vitamin B₁ potency of milk from Toggenburg and Saanen goats with that of milk from Holstein and Jersey cows. They concluded from the rate of growth of rats that goat's milk, which contained 1 international unit of vitamin B₁ in 4 cc. of winter milk and 3 cc. of summer milk, was richer in vitamin B₁ than was the Holstein and Jersey milk, which contained 1 unit in 6 to 7 cc. of winter milk and 5 cc. of summer milk. In a later paper, Besley¹ reported that combined Toggenburg and Saanen milk had a vitamin B₁ content of 28 international units per 100 gm., as compared with 16 units in Holstein milk. Williams, Cheldelin and Mitchell²¹ found in mixed milk from Saanen, Nubian and Toggenburg goats from 0.32 to 0.48 mg. of thiamine per liter, with an average of 0.30 mg.

The thiamine content of the 18 samples of goat's milk used in this study, with the exception of Sample 12, which had a thiamine content of 0.20 mg. per liter, varied from 0.42 to 0.50 mg., with an average of 0.47 mg. This value is significantly higher than that of 0.33 mg. obtained in an earlier study of fresh milk from a herd of Ayrshire, Guernsey, Holstein, Jersey and Shorthorn cows.¹⁰

Effect of Light

It has been frequently observed that exposure to light affects the stability of ascorbic acid, riboflavin and other vitamins. Consequently, a question may arise concerning the possible effect of light on the vitamin content of our samples of goat's milk during the week that had elapsed before they were assayed. During transit they were protected from the action of light by the packages in which they were shipped. While the samples were in the cold-storage room they were subjected to light of approximately 3-foot candles during the day, that is, eight out of twenty-four hours. Thus it seems probable that light had no significant effect on their vitamin content, even though some were shipped in glass bottles and the remainder in paper bottles. As a matter of record, however, the respective vitamin values of the 12 samples packed in glass bottles and of the 6 samples packed in paper bottles were as follows: ascorbic acid, 5.9 and 7.8 mg.; niacin, 2.92 and 3.09 mg.; pantothenic acid, 3.22 and 3.79 mg.; riboflavin, 1.40 and 1.06 mg.; and thiamine 0.48 and 0.40 mg.

SUMMARY

Eighteen samples of goat's milk were procured from producers located within 100 miles of the

laboratory. The samples represented milk produced under routine conditions from normal healthy animals, and were shipped in the usual glass or carton containers, packed in cracked ice. The temperature on arrival was 32 to 40°F. The milk was immediately examined for fat content and bacteria count. The samples were held in a commercial milk refrigerating room until the milk was a week old and then assayed for their vitamin potency.

The average values obtained were as follows: fat, 4.0 per cent; bacteria, 1300 per cubic centimeter; hydrogen-ion concentration, pH 6.37; ascorbic acid, 6.5 mg. per liter; niacin, 2.96 mg. per liter; pantothenic acid, 3.38 mg. per liter; riboflavin, 1.25 per liter; and thiamine, 0.47 mg. per liter.

We are indebted for invaluable assistance to C. Philip Bergstrom, Paul Fay, Duncan M. Gillies, Kay's Goat Dairy, Inc., Malovin's Goat Dairy, Chester A. Meyer, Robert Morter, George E. Stanhope, L. V. Streeter and Herbert F. Wentworth, who supplied the samples of goat's milk and the information concerning the breed and number of goats and their ages, rations and stages of lactation.

The hydrogen-ion concentration of our samples varied from pH 6.13 for Sample 4 to pH 6.62 for Sample 13, with an average of pH 6.37. This value is somewhat lower than those cited above, possibly because the samples were a week old when examined.

Ascorbic Acid

The biologic method was used in the early study of the vitamin C content of goat's milk. Hunt and Winter²¹ fed guinea pigs 20 cc. of cow's and of goat's milk and found a somewhat larger vitamin C activity in the latter. Chakraborty²² assayed the milk of cows, goats, buffaloes and human beings and found 0.009 mg. of vitamin C per cubic centimeter in goat's milk. Richmond, Grinnells and Satterfield²³ examined 430 samples of goat's milk and found a range of 0.5 to 2.0 mg. per 100 cc. Turner and Garrison²⁴ assayed 275 samples of morning milk from twenty-five Toggenburg goats within three hours after milking and obtained an average value of 2.0 mg. of ascorbic acid per 100 cc. Gamble, Ellis and Besley,³ who assayed their samples as promptly as possible after production, obtained a range of 5.0 to 25.0 mg. per liter, with an average of 13 mg., and also observed that the spring and summer milk had more ascorbic acid than did the fall and winter milk. In a comparison of the vitamin C values of cow's, goat's, ass's, mare's and human milk, Cimmino²⁵ found that goat's milk contained 45 mg. per liter and that dehydroascorbic acid was almost entirely absent. In a study of the ascorbic acid content of Indian foods, Rudra²⁶ found that goat's milk contained 0.805 mg. per gram. Wildt and Brouwer²⁷ compared the vitamin C content of goat's and cow's milk during summer feeding on pasture and during stall feeding in winter and found no significant difference. As compared with these values, Frank²⁸ in guinea-pig assays of human, goat's and cow's milk found that human and goat's milk had practically no antiscorbutic properties. This finding was in accord with that of Meyer and Nassau,²⁹ who observed the great increase in the number of cases of infantile scurvy in Germany and made a study of the vitamin content of milk, milk powders and milk products. They found that fresh milk from goats fed green fodder was deficient in vitamin C.

The reduced ascorbic acid content of the 18 samples under consideration was extremely variable. Four samples contained almost no ascorbic acid, and the maximum content was 14.7 mg. per liter. The average value for the 18 samples was 6.5 mg. per liter, but if the 4 small and the 1 large samples are eliminated, the average becomes 7.5 mg. for the remaining 13 samples. These values are lower than those for fresh cow's milk, but they could be anticipated since Hand¹⁰ has reported that the reduced ascorbic acid content of cow's milk decreased from 23 to 7 mg. per liter during six days of storage.

Niacin

Apparently investigators have devoted almost no attention to the niacin potency of goat's milk, for the literature consulted contains only one report of such assays. In their study of the vitamin B content of milk from different species of animals, Williams, Cheldelin and Mitchell³¹ included 4 samples of mixed milk from Saanen, Nubian and Toggenburg goats. They found from 2.0 to 3.2 mg. of niacin per liter, with an average of 2.5 mg.

The values obtained for the 18 samples of milk under consideration varied from 1.79 to 3.81 mg. of niacin per liter, with an average of 2.96 mg. It is of interest to compare the content of goat's and of cow's milk. Williams, Cheldelin and Mitchell³¹ report that goat's milk contains nearly four times as much niacin as does Jersey or Guernsey milk. This relation between goat's and cow's milk is in agreement with that obtained in this laboratory in preliminary experiments.

Pantothenic Acid

A review of the literature concerning goat's milk reveals only one study of its pantothenic acid content. Williams, Cheldelin and Mitchell³¹ examined 4 samples of milk produced by Saanen, Nubian and Toggenburg goats. They obtained a minimum of 1.3 mg. per liter, a maximum of 3.2 mg. and an average of 2.4 mg.

The values obtained in this study ranged from 2.01 to 6.48 mg., with an average of 3.38 mg. In view of the paucity of data, it is hardly possible to compare the pantothenic acid content of goat's and of cow's milk, but Williams, Cheldelin and Mitchell report nearly the same value, that is, 2.9 mg. for cow's milk and 2.4 mg. for goat's milk.

Riboflavin

Gamble, Ellis and Besley³ compared the vitamin G (riboflavin) content of milk from Saanen and Toggenburg goats and from Holstein and Jersey cows by rat-feeding tests at different seasons of the year. They found significant differences favorable to goat's milk. Williams, Cheldelin and Mitchell³¹ determined the riboflavin content of milk from Saanen, Nubian and Toggenburg goats. Their values ranged from 0.89 mg. to 1.2 mg. per liter, with an average of 1.1 mg.

The results obtained in this study of the riboflavin potency of goat's milk were extremely variable, ranging from 0.89 to 2.16 mg. per liter, with an average of 1.25 mg. Aside from Sample 2, which contained 2.6 mg. of riboflavin per liter, all the samples contained less riboflavin than was present in cow's milk.¹⁰ The average value for the goat's milk was 1.25 mg., as compared with 1.51 mg. for raw cow's milk. It should be noted, however, that the cow's milk was fresh and the goat's milk was a week old. Moreover, as stated above, the goat ration was limited in variety and contained no grass

not to be confused with prostitution. The last-mentioned source of venereal infection has been becoming distinctly prominent in the last few years. Many authors have referred to it, and some statistics are now available. Among these is an analysis of 4641 contact reports from the Third Service Command.⁶ Although reported by soldiers in only three eastern states, this large number of exposures took place with girls in all but nine of the forty-eight states. The pickup to whom no fee was paid was the leading source of infection (64 per cent Whites and 45 per cent Negroes), whereas the paid prostitute constituted only one fifth of the sexual contacts. This emphasizes clearly the important role played by "amateurs." Numerous other publications indicate that the fifteen to twenty age group includes the largest proportionate number of these casual female contacts. Obviously the control of juvenile delinquents is extremely difficult to handle through organized authority. Nevertheless, the public-health literature is replete at this time with reports of ambitious plans from state after state; in many instances they are being carried out with reasonable success. Organized control programs are also under way in many large cities. The juvenile delinquency problem, however, will probably not be solved until an understanding of venereal diseases is brought home to each small community; it can then reach the family unit. Not until that point is attained, will we begin to get at the root of juvenile delinquency. Taft⁷ has outlined a seven-point program to attack delinquency, which is based on the same theory. Although he believes that the primary responsibility in meeting the problem lies with the community, it is pointed out that the federal government can do its part. Through the United States Public Health Service three things can be offered in meeting this problem: leadership, funds and trained technical consultants. The duty of the community in rehabilitating delinquents is also portrayed. The value of youth education regarding venereal diseases has been stressed by Bigelow.⁸ The teaching of the significant facts about venereal infections in high schools and colleges is strongly advocated. This author thinks that sexual conduct is determined by ethical attitudes and standards more than by knowledge of scientific facts; consequently, an approach through the home, school, church and youth organizations should have its greatest value in developing character and standards of conduct. Nevertheless, scientific information should prevent some infections and should stimulate many persons to seek medical advice promptly when needed. A number of cities and communities have already included plans for youth education in their control programs. The British Board of Education⁹ has issued a pamphlet on sex education in schools and youth organizations that is extremely well worked out. One in-

teresting suggestion therein is the appointment of "a really good woman physician, preferably married, youngish, with a modern approach and modern clothes" to handle the problem with girls' organizations. More comprehensive attempts are being made to reach the large Negro population in the southern states. There are also numerous reports from Canada and the Latin American countries, which are encouraging. Puerto Rico is one sadly neglected focus of venereal disease in which an organized campaign is now under way. If these programs can be managed more and more effectively, in conjunction with the admirable programs of the military services, much should be learned that will enable everyone to carry on more efficiently when peace finally arrives. An excellent paper by Ingraham and Greenbaum¹⁰ emphasizes the vital part that can and should be played by the practicing physician who treats syphilis. It is pointed out that with the increase in the amount of venereal disease being privately treated, no control program can succeed without full co-operation of physicians in tracing contacts.

Syphilis in Industry

In the past numerous publications in regard to venereal diseases and industry have been quoted, and the current reports indicate continuation of efforts to work through its various branches. This has been done mainly by approaching the medical departments of large corporations. Unfortunately a relatively small percentage of industrial managements has so far been properly educated. In many plants men are still being discharged or refused work if they have syphilis, regardless of the status of their disease.¹¹ One report has been uncovered that indicates an approach through the medium of a labor organization.¹² The Executive Board of the California State Federation of Labor has recommended compulsory blood tests for all future members of the union in California. The co-operation of public-health facilities and the California Social Hygiene Association has been obtained. A thorough educational program is being conducted among the entire union membership. In these days of such constant bickering by some labor groups, it is pleasant to find a good word to say in their favor.

Incidence of Syphilis

Statistics for the fiscal year 1943-1944 for all the states, territories, possessions and the Panama Canal Zone are now available.¹³ For the United States proper, 100,000 fewer cases of syphilis of all kinds were reported. In only thirteen states was there an increase, and in but four of these was it significant. These figures are compiled from the health officers' monthly statements and do not include the armed forces. Army data indicate that the rate of venereal infection has fallen below preceding peace-

MEDICAL PROGRESS

SYPHILIS

G. MARSHALL CRAWFORD, M.D.*

BOSTON

PENICILLIN appears to be capable of playing as dramatic a role in the treatment of syphilis as in numerous other infections, if early indications are correct. This is the outstanding feature of progress in regard to syphilis during the past year. The incidence of this disease has been notably reduced, even without the aid of penicillin — a remarkable feat in time of war.

PUBLIC-HEALTH ASPECTS

In these columns six years ago it was stated that the chance of acquiring syphilis during the average lifetime was approximately 1 in 10.¹ Vonderlehr and Usilton² computed this 10 per cent attack rate from figures covering the years 1936 and 1937. The same authors have made a second appraisal covering the years 1939 to 1941.³ Their data were obtained from the number of persons with early syphilis reporting for the first time at authorized sources of treatment that serve about 5 per cent of the population. The second survey showed that the chance of persons acquiring syphilis by the age of fifty had dropped to 1 in 15, a decrease of one third. This study clearly indicates that during the six-year period 1936-1941 the chance of acquiring syphilis dropped appreciably. These two sets of data should serve as a base line by which the control of syphilis in the future may be judged. The years covered in these surveys are those during which the campaign for the control of syphilis was being intensified. Although the decrease in the attack-rate of syphilis is indeed gratifying, it should be recalled that the United States in 1940 had not yet entered World War II. Turner⁴ has reviewed the accomplishments

in the control of venereal diseases since 1940. His figures indicate a striking reduction in the level of days lost per man per year because of venereal diseases in the armed forces. In 1940, as many as 1278 days were lost per 1000 men per year, whereas at the time of Turner's writing (1943) the rate was 368 days per 1000 men per year. He credits most of this magnificent accomplishment to the work of venereal-disease control officers who were assigned to camps and to all theaters of operations. This is an example of intelligent utilization of specially qualified medical personnel. Turner believes that a civilian program designed to control venereal diseases should be similarly built around medical specialists in this field. The tasks that lie ahead of the military in respect to venereal diseases are outlined. A public-health step of first importance has been taken by Congress.⁵ A new law abolishes all punishment for venereal disease in the armed forces, provided only that the infected person complies with Army or Navy regulations requiring him to report and receive appropriate treatment. Failure to report a venereal infection remains punishable by court-martial or other disciplinary action. This measure recognizes that fear of punishment does not prevent exposure but does promote concealment and self-treatment.

Juvenile Delinquency

Turner⁴ also stresses the expansion of educational efforts, particularly those directed to the young women of the community, the maintenance of the gains made against organized prostitution and the problem of the sexually delinquent girl, which is

*Instructor in dermatology, Harvard Medical School; assistant dermatologist, Massachusetts General Hospital.

considered adequate therapy. It poses the question whether the correct definition of adequate therapy is actually known.

Six cases of acute encephalopathy were encountered by Young and Gordon.²⁵ These patients were being treated with a heavy-dosage, multiple-syringe, intensive schedule. All received the conventional therapy for hemorrhagic encephalitis, but only one patient recovered. The clinical pictures and autopsy reports are given. Typical necropsy findings were edema and numerous petechial hemorrhages of the entire brain, slightly larger hemorrhages in the pituitary gland, cloudy swelling of the liver and congestion of the kidneys and alimentary canal. This particular reference is quoted to emphasize one of the grave disasters that may be encountered in massive-treatment programs. A distressingly high percentage of all types of treatment reactions is still being observed, even with the modified intensive schedules that are in general use in military stations, governmental treatment centers and many large civilian hospitals. All this work must still be considered experimental, as has been repeatedly emphasized in the past. Any physician treating syphilis is frequently besieged by his more alert patients with inquiries about, or demands for, rapid treatment. It is unfortunate that the lay press is so prone to publicize experimental medicine.

DIAGNOSIS

Serologic Tests

In an editorial, "The Serology Was Positive," Moore²⁶ makes a plea for a correct usage of terminology. He points out that "serology" is a branch of science and not a test. It is a term that cannot be limited to diagnostic tests for syphilis, nor can serology be expressed as "positive" or "negative." It is pointed out that the correct expression is "the serologic test was positive." Moore goes on to call attention to the fact that the adjective "serologic" is not applicable to spinal fluid tests, as this fluid is not a serum. It may be added that a commonly accepted abbreviation for the term "serologic tests for syphilis" is "STS." This will be seen in much of the literature pertaining to syphilis at the present time. It is always correct, in addition, to name the actual test employed, if one so desires.

For several years the Kahn verification test has been employed in some laboratories in an attempt to detect false positive tests in routine serologic practice. Kahn²⁷ has continued his work with this special test and has introduced improvements. He has determined differential characteristics of specific and nonspecific serologic reactions with different temperature and electrolyte requirements. These procedures "type" serodiagnostic reactions on the basis of their specificity. The verification test may give false positive cases that are free

from clinical indications of syphilis. If nonspecific type reactions are found in the absence of any history or clinical evidence of syphilis, Kahn believes that the positive reactions are nonspecific and syphilis can be ruled out. This is certainly a step in the right direction. If this work is corroborated, and if the verification test becomes widely available, it should be of considerable value.

An English Navy innovation has been reported by Crick,²⁸ who recommends the use of serologic precipitation tests for syphilis aboard large ships in wartime. This procedure has proved of value in dark-field-negative lesions and suspicious eruptions. It has also relieved the hospital ships in routine blood examinations. It is not advocated to the exclusion of hospital laboratory tests, but is recommended as an adjunct in certain circumstances.

False Positive Tests

An analysis has been made by Kolmer²⁹ of the results of nine serologic surveys from 1935 through 1941. A large number of the false positive reactions in the serodiagnosis of syphilis were found to have been due to errors in the collection of blood, resulting in excessive contamination or hemolysis, and to faulty laboratory technic. Technical errors inherent in the tests themselves may give false indications even in skilled hands. Comparing the results of these various serologic surveys with another in 1943, Kolmer found an appreciable decrease in the percentage of false positive reactions in serums of normal nonsyphilitic individuals. The author classifies the diseases and conditions known or suspected of causing biologic false doubtful and positive reactions into three groups. First, a variable incidence is seen in yaws, pinta, leprosy, malaria, vaccinia and vaccinoid, infectious mononucleosis and virus pneumonia. A second group of ten febrile diseases is stated to show an unknown incidence. A still larger third group of conditions is mentioned in which the evidence regarding false positive tests is not conclusive. A listing of these two latter groups will be omitted to avoid confusion; it is suggested that suspected false positive reactions occurring in diseases other than Kolmer's first group be subjected to exacting scrutiny. In Kolmer's paper it is stressed that the entire responsibility of the diagnosis of syphilis should not be placed on the laboratory findings and that there is no substitute for thorough clinical examination. In cases in which the reactions are persistently positive it is frequently advisable to make a tentative diagnosis of syphilis and institute treatment. This is particularly true if the positive reports come from more than one laboratory and by multiple technics. A situation such as pregnancy is an additional indication for treatment.

It seems apropos at this point to enumerate a few suggestions for the prevention of hemolysis of blood specimens. The syringe and needle used to draw blood should be dry and sterile. Alkalies and other

time levels and is less than half that recorded during World War I.¹⁴ If this trend continues, it will be the first war in history during which syphilis has been held in check. This applies to the general public and even more remarkably to the military services.

EXPERIMENTAL STUDIES

Further studies of *Treponema pallidum* by the electron microscope are available. Mudd, Plevitzky and Anderson¹⁵ have compared several strains with other spirochetes and confirmed the findings of previous students. Cares¹⁶ has reported on the differential motility characteristics of *T. pallidum*. His material was obtained from infectious lesions rather than from cultures. Three other forms of spirochetes were encountered. The identifying motility types of locomotion and changes in shape are carefully described. Although this work was done with the use of the electron microscope, a good deal of the motility of *T. pallidum* can be observed with an ordinary microscope. A review of this article should be beneficial to any practitioner capable of and equipped to do dark-field examinations.

An interesting study has been reported regarding the effect of fever on the distribution of arsenic in the tissues of rabbits injected intravenously with Mapharsen.¹⁷ It was found that there were distinctly higher concentrations of arsenic in the tissues of rabbits treated with Mapharsen and fever than when the former was given alone. Observations made twenty-four hours after treatment revealed that significant amounts of arsenic were still present in all the tissues in the fever-treated group; whereas in the group receiving Mapharsen without fever only negligible amounts of arsenic could be detected in tissues other than the kidneys and lungs. These findings suggest that fever may either bring about an increased deposition of the drug in the tissues or fix it more firmly, thus delaying elimination. Both factors may of course be involved. These observations may explain the enhanced therapeutic action of arsenical drugs when combined with fever, and perhaps also the increase in toxic reactions.

Many reports have appeared in recent years regarding the use of ascorbic acid as a detoxifying agent during treatment with intravenous arsenical compounds. During the last year several publications have appeared on detoxication by means of *p*-aminobenzoic acid. Sandground^{18,19} carried out extensive experiments with rats. Massive acutely poisonous doses of several pentavalent arsenical drugs were used. The survival rate among rats that received *p*-aminobenzoic acid as compared with that of controls was so high that its protective role seemed established beyond question. Furthermore, there appeared to be no inhibition of the trypanocidal action of the arsenic. Subsequently, Sandground and Hamilton²⁰ carried out parallel experiments

with lethal doses of neoarsphenamine and found the protective capacity of *p*-aminobenzoic acid equally effective. The clinical implications of these findings, especially with respect to the intensive treatment of syphilis, seemed promising, but when this work was applied clinically, the results were discouraging.²¹ A small group of patients with neurosyphilis were given *p*-aminobenzoic acid in conjunction with pentavalent arsenical compounds. Such oral administration, however, did not prevent nitritoid crises, gastrointestinal reactions or optic-nerve damage. This apparent failure may not be as disheartening as it sounds, and one can still hope for more satisfactory results with further work. Another group of investigators,²² studying the detoxifying actions of several organic acids, confirmed Sandground's findings in experiments on animals. It was further observed that the effect is most favorable when the arsenical and the protective agent are injected intravenously in the same solution.

PATHOLOGY

Although comparatively little medical literature has been available from Germany in recent years, one quite interesting report has turned up. Gottschalk²³ quoted the Magdeburg combined morbidity statistics for the period 1928-1936 regarding venereal diseases as a cause of death. These statistics include 8182 deaths for which both the clinically determined cause of death and autopsy findings were available. Of this number 322 (3.9 per cent) died of disease that was clinically diagnosed as syphilis, and in 214 of these (66 per cent) the clinical diagnosis was confirmed by autopsy findings. Another 192 cases were found in which the autopsy determined syphilis to be the cause of death, bringing the total number to 406 cases of death due to syphilis. By means of autopsy, therefore, 26 per cent more cases were diagnosed in which death was due to syphilis than by clinical findings alone. Aneurysm and tabes dorsalis were the two syphilitic conditions most frequently incorrectly diagnosed clinically. Black-Schaffer and Rosahn²⁴ report a continuation of their study of autopsy reports from Yale University School of Medicine. An attempt was made to correlate the serologic tests for syphilis in 313 autopsies on syphilitic patients. Serologic positivity was significantly more frequently associated with anatomic lesions of syphilis than was serologic negativity. Analysis of the data from numerous standpoints suggested that increasing activity of the disease is associated with an increasing frequency of positive blood tests. The likelihood of syphilis being the primary cause of death was more than twice as great in patients with positive serologic tests than in syphilitics with negative tests. These findings are quite interesting in view of a strong tendency among syphilologists to disregard the so-called "serofast status," which not infrequently persists in late syphilis even after what is

penile lesions observed by Loveman and Morrow.³⁹ The urethral discharge in these cases should be serosanguineous or seromucoid, as contrasted to the thick purulent discharge seen in gonorrhea. Mild symptoms of obstruction to the flow of urine may be present. Here again, painless indurated nodules should be palpable. Dark-field examination from the discharge or from the regional lymph nodes should be positive.

Lymph-Node Puncture

Loveman and Morrow,⁴⁰ have also stressed the value of dark-field examination of lymph nodes in the diagnosis of early syphilis. Twenty-three of 25 cases of early syphilis yielded positive findings by this method. In 12 (60 per cent) of 20 cases dark-field examination from the local lesions resulted in negative findings. A general discussion of technic is given. Agee⁴¹ writes in a similar vein and points out the value of lymph-node puncture in patients whose satellite nodes persist after the healing of the primary lesion. He has found positive dark-field examinations after as much as eight weeks' intensive therapy. This might arouse speculation regarding the value of one of the commonly used criteria of the effectiveness of early treatment. The rapidity with which surface lesions become dark-field negative under various forms of treatment is stressed as an indication of the effectiveness of therapy. Agee's article indicates that viable organisms may be found in lymph nodes after many weeks of intensive treatment. This should stimulate more thought and conservatism in acclaiming the value of intensive therapy. Twenty years from now we may be disappointed in present-day methods, including the magic of penicillin. There may be more value than we realize in prolonged courses of treatment for syphilis.

Bone Syphilis

Francis and Kampmeier⁴² have reported an interesting study of bone lesions found in late acquired syphilis. Roentgenographic evidence of the disease was found in one hundred and seventeen bones in a series of 67 patients. The order of frequency of the most usual sites of bone involvement was as follows: tibia (29 per cent), clavicle, skull, fibula and femur. Lesions were found in twenty different bones. The pathologic findings of tertiary syphilis of the bone are described. In the series reported, periostitis, gummatous osteitis and sclerosing osteitis were found. The amount of bone syphilis reported by these men is much greater than is commonly observed. It must be remembered, however, that they were seeking this one feature by routine x-ray studies rather than by clinical means.

Syphilis of Stomach

Although syphilis seldom produces gastric lesions, it is a diagnosis that may be easily missed. Cunha⁴³

has recently published his observations on this topic. He believes that a positive serologic test in a patient with gastric deformity demonstrated by x-ray calls for an immediate re-evaluation of the gastric diagnosis. It is pointed out that there is no reason why a syphilitic patient cannot have a malignant neoplasm and that a benign ulcer can also occur in a syphilitic person. Diagnostic features that point toward syphilis of the stomach are outlined as follows: an unduly long history of illness, comparatively mild anemia, higher free-acid values than usual, the absence of gross and occult blood, and extensive tissue involvement as seen by x-ray. Cunha has observed 9 cases of syphilis of the stomach.

Syphilis of Liver

An excellent study of syphilis of the liver has been reported by Hahn.⁴⁴ His data on 1165 adult syphilitic patients were obtained from autopsy material at the Johns Hopkins Hospital over a period of nearly thirty years. He found no autopsy report of early syphilis of the liver. The incidence of late syphilis of the liver among the syphilitic patients was 4.9 per cent. The most outstanding pathological finding was the focal gummatous nature of late hepatic syphilis. An analysis of the clinical findings, verified by pathological reports, revealed that no single manifestation was constantly or even usually present. Abdominal pain seemed to be the most significant subjective complaint. The most frequent physical finding was a palpable liver. The spleen was also palpable in many cases. The blood was seropositive in 81 per cent of the patients. Not one patient with late syphilis of the liver had received adequate therapy for early syphilis. The median estimated duration of syphilis was fifteen years. The correct hepatic diagnosis had been suggested in only 12 per cent of the total. Portal cirrhosis and carcinoma of the liver accounted for over 50 per cent of the erroneous diagnoses. It was found that hepatic syphilis rarely produces ascites, huge livers, pronounced weight loss, high septic fever or severe toxemia. There was no evidence that liver damage due to syphilis predisposed to hepatic injury from arsenicals. Portal cirrhosis rarely occurred in association with definite hepatic syphilis. This is a thorough study that merits careful scrutiny by internists as well as physicians in general practice, even if they have no interest in or do not treat syphilis.

Cardiovascular Syphilis

More publications than usual have appeared on the various phases of this topic during the past year. Many are of general interest, whereas others seem to be of value mainly to cardiologists, who deal with the obtuse facets of cardiovascular disease.

Mattman and Moore⁴⁵ point out that, although uncomplicated syphilitic aortitis is often an asymptotic

chemicals should be avoided if syringes are boiled. Blood should never be sprayed through the needle into the tube; the needle should be detached, and the blood should be expelled slowly against the side-wall of the tube. The tube should be placed in a cold place at once, preferably in a refrigerator, especially in warm weather, and should be kept there until mailed. These procedures will help to reduce the number of anticomplementary specimens.

In previous progress reports, references to false positive tests after smallpox vaccination have been quoted. Further confirmation of this observation has been published by Favorite.³⁰ A group of 202 medical students and nurses known to have negative serologic tests were vaccinated and repeatedly tested, using three technics. Twenty-four persons (11.8 per cent) were seropositive at some time following the vaccination. These cases were retested every two weeks. There was a gradual diminution of reactions, with all becoming negative by the end of one hundred and twenty days.

A group of investigators at the Iowa State Laboratory³¹ studied the reactions in the serums of 993 known syphilitic persons by three technics. It was found that 13.5 per cent gave entirely negative reactions for all three tests and that 9.7 per cent gave contradictory reactions. It is a frequent observation that these contradictory reactions may persist or may disappear, with or without antisyphilitic treatment. These authors offered several explanations for the disappearance of contradictory reactions. It is stated that they may be due to the development of a latent nonreacting stage of the disease, to a spontaneous cure or to causes other than syphilis that cease to exist. The authors think that the last explanation is the most probable and cite a number of cases to substantiate their belief. This spontaneous reversal to a negative state may require a period of weeks or months. It is again stressed that physicians should not base their diagnoses solely on serologic reports.

The responsibility of ruling out syphilis is equal in importance to that of diagnosing it. Taussig³² reports in this vein and quotes illustrative cases. He offers a list of suggestions to avoid errors in diagnosis in patients who show no other evidence of syphilis than a repeatedly positive serologic test. One point to bear in mind is the fact that serums positive with less sensitive technics, such as the standard Wassermann test, but negative with highly sensitive tests are probably not syphilitic. An instance of false positive serologic tests for syphilis in several members of a family has been reported.³³

It is quite universally accepted that cerebrospinal fluids are much less likely to yield false positive reactions. This may indicate that the reagin-like substances that are thought to occur in the blood serums of nonsyphilitic persons yielding false positive reactions do not occur in cerebrospinal fluids.

An article has appeared, however, reporting 8 cases with false positive spinal-fluid Wassermann reactions.³⁴ Seven of these occurred during the course of meningitis. In 5 cases two different organisms were cultured from the spinal fluid; 2 were aseptic. In 7 of the cases the blood was seronegative.

CLINICAL PROBLEMS

Early Syphilis

An interesting study of 2451 newly inducted soldiers revealed a surprising amount of syphilis.³⁵ All had been classified 1-A by an induction board and were presumably free of venereal disease. Fifty-five men were found to be definitely syphilitic: 4 had early syphilis; 8, neurosyphilis; and 43, latent syphilis. An additional 61 men were thought to have had previous syphilitic infection and to have been cured by treatment. Only the 4 men with early infection showed physical evidence of the disease, and only 10 of the others had a doubtful or positive serologic test. This indicates the importance of an adequate history in conjunction with serologic testing and physical examination. A good discussion of the principles of diagnosis in syphilis and the comparative merits of available procedures has been given by Barnett.³⁶ The importance of meticulous examination is stressed. The ease with which minor bits of clinical evidence may be overlooked is well illustrated.

As in many other diseases, the failure to make a diagnosis of syphilis may often be due simply to not thinking of its possibility. Bearing the disease in mind is of utmost importance with early lesions in the seronegative stage. An interesting commentary on this point has been published by Spatz.³⁷ This author reports a series of 11 consecutive cases of primary syphilis in which only 3 presented the classic type of painless, hard, solitary chancre. The lesions in the remaining cases resembled the ordinary chancroidal or balanitic ulcerations; they were not indurated, often were multiple and sometimes were painful. All these cases were diagnosed by dark-field examination. The question is brought up how many latent or advanced cases of syphilis were not detected in their early stages simply because the primary lesions were so atypical or minor as not even to suggest syphilis to the examiner. Each and every case with a genital ulcer of any description should be subjected to dark-field examination. This applies likewise to many lip and mouth lesions.

The misleading appearance of a meatal chancre has been stressed by McCarthy.³⁸ It often suggests a mild or recurrent gonorrhea. In the earliest stages it may even appear to be an abortive herpes genitalis. Induration eventually becomes evident, however, and is a sign of utmost diagnostic importance. If the possibility that the lesion is syphilitic is recognized, the problem should be simple. Intraurethral chancres occurred in 8 (11 per cent) of 70 patients with

types. Aring⁵⁴ has also written on acute syphilitic meningitis. He is in general agreement with the preceding author and stresses the importance of intensive therapy. It is pointed out that tryparsamide or fever therapy may be required in some cases.

Syphilis of the spinal cord is discussed at considerable length by Adams and Merritt.⁵⁵ These authors classify and discuss spinal syphilis based on pathologic changes. They point out that a pure form of spinal syphilis without lesions of the brain is exceptional, and state that the basic pathologic lesion is probably chronic inflammation of the spinal meninges. Almost every conceivable cord disease may be simulated clinically by spinal syphilis. The authors believe that the introduction of any foreign substance intrathecally, whether a spinal anesthetic or arsphenamized serum, in a patient who has neurosyphilis is dangerous. The clinical results in the treatment of spinal neurosyphilis are discouraging.

The Medical Corps of the Army has set up a special program for the management of neurosyphilis.⁵⁶ Certain general hospitals are designated as treatment centers, and all cases diagnosed as neurosyphilis are transferred there for diagnostic review and treatment. It is expected that the bulk of cases will be asymptomatic, with minor spinal-fluid changes, will respond relatively quickly to therapy and will be retained in military service. All other cases will be separated from the service after optimum treatment. Thereafter the United States Public Health Service will maintain observation and treatment as indicated.

(To be concluded)

matic disease, the extent to which this is true varies not only with the skill and diligence of the clinician but also with the extent of pathologic damage to the aorta. These authors compare two groups of patients observed at the Johns Hopkins Hospital. In a series of 105 patients found at necropsy to have uncomplicated syphilitic aortitis, the clinical diagnosis had been correctly made or suspected before death in only 41 per cent. The authors then add an additional series of 79 patients, observed ten years later, in which the incidence of correct clinical diagnoses had increased to 68 per cent. This appears to indicate that Moore's criteria for the clinical diagnosis of uncomplicated syphilitic aortitis are valid. A keener appreciation of them will, of course, increase the percentage of accurate diagnoses. Hypertension, extensive arteriosclerosis and rheumatic heart disease must, if possible, be ruled out. Moore emphasizes the following symptoms and signs in the diagnosis of syphilitic aortitis: roentgenologic demonstration of dilatation of the first portion of the aorta; heart failure or lowered cardiac reserve in the absence of other causes; localized substernal pain (to be differentiated from anginal pain); and characteristic changes in the aortic second sound. Dressler and Silverman⁴⁶ write in a similar vein on the same topic. The interesting feature of their report is the finding of syphilitic aortitis in 8 of 50 cases of congenital syphilis. It is their belief that this condition is more frequent in congenital syphilis than has heretofore been held.

Jones and Bedford⁴⁷ describe a series of 103 syphilitic patients subject to paroxysmal pain in the chest that was investigated with special regard to its clinical characteristics. The average period between infection and the onset of pain was twenty-four years. The clinical findings included varying degrees of dilatation of the aorta, cardiac enlargement, aortic incompetence and essential hypertension. Seventy-six patients suffered angina on effort, and 64 had pain apart from effort. Nocturnal attacks were of common occurrence and were usually independent of paroxysmal dyspnea. Symptoms of coronary thrombosis not attributed to syphilis occurred in 10 cases. Post-mortem findings are reported on 12 cases. Pathologic evidence that uncomplicated aortitis causes anginal pain was lacking. Stenosis or occlusion of the coronary ostia was usually found in conjunction with typical syphilitic lesions, but it is stated that atheromatous and thrombotic coronary occlusion may be coincident with syphilis of the aorta. These authors do not believe that an atypical or pseudoanginal syndrome due to syphilitic aortitis exists.

It is stated by Arkin⁴⁸ that syphilis is responsible for about 20 per cent of the cases of chronic cardiac disease in adults. This author stresses the preventable nature of syphilitic heart disease, and estimates that early diagnosis and adequate treatment should prevent at least 90 per cent of cases of cardiovascular

syphilis. He stresses the need for a periodic physical examination and roentgenographic study of every patient with evidence of syphilis. Arkin's criteria for the diagnosis of uncomplicated aortitis are slightly more elaborate than those of Mattman and Moore.⁴⁵ Aortic insufficiency is discussed at some length by Hammon.⁴⁹ Syphilitic aortic insufficiency is one of the eight groups into which this author divides these cases. He points out that repeatedly negative serologic reactions occur in from 10 to 15 per cent of cases of syphilitic aortitis. The clinical diagnosis is elaborated in some detail, and the author describes several interesting cases in which syphilis was a factor of the incorrect diagnosis.

Jones and Bedford⁴⁷ found abnormal cardiograms in 57 of 94 syphilitic patients subject to paroxysmal pain in the chest. Cole and Bohning⁵⁰ paid special attention to electrocardiographic patterns in cardiovascular syphilis. They have correlated the post-mortem findings and electrocardiograms in 30 cases. No specific pattern was found to be pathognomonic of syphilitic cardiovascular disease, but there were 11 cases of left ventricular preponderance and 3 cases with an anterior-wall infarction pattern. These seemed frequently due in whole or in part to syphilis. Parsonnet and Bernstein⁵¹ wrote on the same topic. They consider the electrocardiogram of vital importance as a diagnostic, prognostic and therapeutic guide in cardiovascular syphilis, but state that a diagnosis cannot be made from it alone. They also point out that some of the methods of treatment are factors in initiating cardiographic changes that are indicative of myocardial damage.

Neurosyphilis

O'Leary and his associates⁵² have published an excellent analysis of the spinal-fluid findings in asymptomatic neurosyphilis. A general classification of spinal fluids is given in tabular form, according to the degree of abnormality observed in each of the five usual tests. Thus the character of the impending nervous-system involvement may be anticipated and the progress of the disease and the effect of treatment may be properly estimated. It is stated that if the spinal fluid is still negative by the fourth year of the disease, neurosyphilis will probably not develop.

Although acute syphilitic meningitis is a comparatively uncommon complication of syphilis, 15 cases are reported by Skogland.⁵³ It is pointed out that acute meningitis usually occurs in early syphilis and in untreated or inadequately treated patients. The author states that the blood Wassermann reaction is negative in approximately a third of the cases. Three clinical pictures may be seen: acute hydrocephalus, acute meningitis of the vertex and acute basilar meningitis. Recovery is usually prompt with proper treatment, trivalent arsenic being the initial choice, but sequelae may occur. The author's cases illustrated the three different

Dr. Holmes has just arrived and I need him. Since time is short, I shall put it up to him this way. If you glance at the first paragraph in the abstract you will see that for twelve years this woman was apparently coughing up purulent sputum, which for a year had often been bloody. She raised as much as a cupful; it smelled bad but later it states that x-ray examination was negative.

DR. GEORGE W. HOLMES: That is correct.

DR. MEANS: I have a case of tuberculosis in mind in which the x-ray films were reported to be negative for tuberculosis.

DR. HOLMES: That is unusual. About the only time when x-ray films are negative in pulmonary tuberculosis is when the lesion is in the bronchus. You can have an ulcerating lesion in the bronchus with tubercle bacilli in the sputum and a negative x-ray film. You cannot have parenchymal tuberculosis and a negative x-ray film.

DR. MEANS: One of the wisest men on diseases of the chest, under whom I was fortunate enough to be a student, was the late Dr. Frederick T. Lord. He said that any patient who had a story of this sort must have a chronic bronchopulmonary suppurative process of some kind. If not in the lung, at least in the bronchus.

DR. HOLMES: Do not let me mislead you. The fact that the x-ray films are negative does not prove that the patient did not have a lesion in the bronchus.

DR. MEANS: I know that very well. The answer is that the radiologist cannot necessarily determine a lesion of the bronchus.

According to Dr. Lord's philosophy, if I remember it correctly, this woman ought to have a chronic lung abscess or bronchiectasis. It is too long a history for abscess, however. A lung abscess would have cleared up or would have killed her by that time; therefore it must be bronchiectasis. Dr. Holmes could not demonstrate bronchiectasis, I suppose, if the cavities were empty. Is that correct?

DR. HOLMES: We miss a certain number of cases but this woman's chest is entirely normal. I hardly think that she could have had bronchiectasis.

DR. MEANS: How could she have raised a cupful of foul-smelling sputum daily for twelve years and not have had anything in the chest? Had she a fistulous tract that fed pus into the bronchus from somewhere else?

DR. HOLMES: We do not know whether the observation was accurate. The material may have come from the stomach.

DR. MEANS: The gastrointestinal tract was reported negative by x-ray study.

DR. HOLMES: The x-ray films do show a large liver.

DR. MEANS: I am going to get to that. Let us stick to the thorax for the moment. I was thinking about the esophagus and the bronchus. Are they mixed up with one another or connected in some unholy alliance?

DR. HOLMES: If they are, we have no evidence of it.

DR. MEANS: She was said to have vomited blood and, unless it is a perfectly erroneous history, I am forced to conclude, x-ray or no x-ray, that she either had or had had some sort of chronic bronchopulmonary suppurative process. I do not believe that these facts fit with any other interpretation, and a little thing like a negative x-ray should not shake one in one's argument if one thinks that the premises are sound. We are told that she was vomiting. If this was all gastrointestinal in origin it seems to me that Dr. Holmes ought to see something in the gastrointestinal tract beyond a little pushing of the liver in a southeasterly direction. What can you tell about the gastrointestinal tract, Dr. Holmes? Is there anything else besides the pushing down of the liver?

DR. HOLMES: I did this examination myself and that is all I could or can see.

DR. MEANS: But you are willing to say that the liver is big.

DR. HOLMES: Yes.

DR. MEANS: There have been cases in which the radiologist has said that the liver was big and the clinician has said that it was not big, and Dr. Castleman has found that sometimes the radiologist was right and sometimes the clinician was right. But here both the clinician and the radiologist thought that the liver was big; ergo, I shall say that the liver was big. Of course if the patient had a chronic bronchopulmonary suppurative process with a big liver she is entitled to have had amyloid disease, but I do not think that amyloidosis would explain the acute picture of severe pain in the right upper quadrant.

I have said all I need to say about the lung situation. I do not believe that it was tuberculosis.

In these exercises we usually try to explain the whole picture on the basis of a single underlying disease. We are taught that that is the right thing to do in differential diagnosis. If you stick too rigidly to it, however, you come a "cropper" a certain number of times, because a person can have two diseases. Whether the five-day story of abdominal pain has anything to do with the thoracic story, I do not know. I suppose we should try to relate it, but it does not have to be related. One thing is evident. I am sure that she had an avitaminosis, which explains the stomatitis, the raw red tongue, the sensory changes, the reflex changes and so forth. The clinicians gave her high-powered vitamin therapy, so evidently they thought the same.

On physical examination we are told that this woman was well nourished, although she had lost weight. She might have been overweight to start with. I do not know why she did not look sick. She was said to be exhausted and was forced to stay in bed. Sometimes neurotics take to bed, but she was not neurotic I should say. I do not know

CASE 31031

PRESENTATION OF CASE

A twenty-nine-year-old woman was admitted to the hospital complaining of a chronic productive cough and abdominal pain.

Twelve years prior to admission the patient began to suffer with chronic cough. This was often accompanied with fever and was productive at times of as much as a cupful of mucopurulent, foul-smelling sputum a day. The sputum was never blood streaked until a year before entry, when flecks of blood were first noted. The cough and streaking became increasingly severe and were associated with vomiting, often at the end of a paroxysm. On several occasions she vomited intractably for several days at a time. On two occasions she was said to have vomited blood, although at no time did the vomitus have a coffee-grounds appearance. About six months prior to entry a bronchoscopy and lipiodol study were performed, following which she felt better for a few weeks. The blood streaking of the sputum increased, however, until it occurred daily and was most marked in the morning. About three weeks prior to admission she became so exhausted that she was forced to remain in bed; the slightest exertion often induced a severe paroxysm of coughing followed by vomiting. She was able to retain little food, and the tongue and mouth became sore. She had lost about 16 pounds during the year before entry. Five days before admission she developed severe pain under the costal margin in the right upper quadrant, radiating to the epigastrium but not to the back. The pain occurred intermittently in attacks lasting up to twelve hours. There was no diarrhea, constipation, abnormal stools or jaundice. She was admitted to the hospital for study.

The patient had been married for three years but had been unable to become pregnant. She had been a heavy smoker but had cut down considerably in the few months prior to admission.

Physical examination revealed a well-developed and well-nourished woman who did not appear particularly ill. The tongue was beefy red and moderately smooth. The mouth contained numer-

ous small ulcers on the mucous membranes. The lungs revealed only a few medium moist rales at the bases. The heart was negative. There were considerable tenderness and muscle spasm in the right upper quadrant. A tender mass, believed to be the liver, was palpable in this area, extending down almost to the level of the umbilicus; no definite edge could be felt. The spleen was not palpable. There was a lack of precise differentiation between sharp and dull sensations in the lower legs, and some questionable loss of position sense. Vibration sense was diminished in the left lower leg. The deep tendon reflexes were present but the ankle jerks were weak. The plantar responses were not elicited.

The temperature was 99.4°F., the pulse 100, and the respirations 24. The blood pressure was 120 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 11,200, with 93 per cent neutrophils, 4 per cent monocytes and 3 per cent eosinophils. The hemoglobin was 11.8 gm. The urine had a specific gravity of 1.028, with a ++ test for albumin; the sediment contained a few red cells, 15 white cells and a rare granular cast per high-power field. The stools were brown, and a guaiac test was negative. The serum nonprotein nitrogen was 23 mg. per 100 cc., the sugar 78 mg., the protein 6.4 gm. and the chloride 94 milliequiv. per liter. The van den Bergh reaction was normal. The prothrombin time was 24 seconds (normal, 18 to 20 seconds). A bromsulphalein test showed 40 per cent retention of dye in forty-five minutes.

A roentgenogram of the chest was within normal limits. A gastrointestinal series revealed displacement of the stomach to the left and downward displacement of the hepatic flexure of the colon, but was otherwise negative. The lower border of the liver was not well demonstrated. An intravenous pyelogram revealed only a low right kidney. A Graham test was negative.

The patient was given numerous infusions of dextrose in saline together with vitamin B complex, haliver-oil capsules and hykinone. The white-cell count rose to 25,600, with 79 per cent neutrophils, 11 per cent lymphocytes, 8 per cent monocytes and 2 per cent eosinophils.

On the nineteenth hospital day a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. J. H. MEANS: "About six months prior to entry a bronchoscopy and lipiodol study were performed, following which she felt better for a few weeks." Are you holding back what was found?

DR. BENJAMIN CASTLEMAN: That is all that is in the record.

DR. CHESTER M. JONES: It was done elsewhere.

DR. MEANS: Apparently no Hinton test was done but I do not believe that the patient had syphilis.

acute surgical emergency. When I saw her she did not look so well as this record implies. She appeared extremely sick and was nauseated and vomiting; the white-cell count was 25,000, with 93 per cent neutrophils. She had definite spasm and tenderness in the right abdomen. I could not make a diagnosis, nor did I believe that she was sick enough to warrant immediate surgical operation.

DR. MEANS: Did you think that she had intestinal obstruction?

DR. MEIGS: No; I thought that she might have had a chronic rupture of some viscus. There was a mass on the right side. I could not feel the edge of the liver. All I knew was that we ought to get her some place where we could follow her closely. She was brought here. The next morning she looked better and the white-cell count had dropped. I thought that she had some disease connected with the liver. I asked Dr. Jones to see her. We thought that it was some sort of medical problem quite definitely connected with the liver. I did not believe that the pulmonary difficulties had anything to do with it. Dr. Richard H. Overholt had bronchoscoped her and found bronchiectasis. Dr. Jones carried on.

DR. JONES: By the time I saw the patient there was little in the chest except for a few rales, particularly at the right base. We all thought that she had a low-grade bronchiectasis to account for part of the clinical picture, but we did not believe that it had caused the symptoms that brought her to the hospital. She had a large mass, which Dr. Meigs and I both thought was probably a large liver. It was extremely tender for two weeks after admission to the hospital. We could not be certain whether the tenderness was along the hepatic border or underneath the edge of the liver. As she improved, with adequate hydration and rather intensive vitamin therapy for obvious avitaminosis, it became clear that the tender mass actually was liver. The one test that gave us a direct clue was the brom-sulfalein test, with 40 per cent dye retention in the absence of jaundice. Dr. Meigs and I decided that the sensible thing to do was to sit tight until she got better and then make absolutely certain that there was no disease besides the intrahepatic disease. For that reason she was explored.

The patient was explored with the idea that she had a subacute inflammatory, possibly cirrhotic, process in the liver, not necessarily on an infectious basis. We did not expect to find anything outside the liver. We simply wanted to make certain.

DR. MEANS: The chief point of disagreement between Dr. Jones, who saw the patient and therefore had more information, and me is whether the process in the liver was acute or subacute. There is nothing in the abstract on which I could say that it was other than acute. I did have cirrhosis down here on my list of differential diagnoses but forgot to mention it. You have to think of it because it is

a frequent liver disease producing a great variety of pictures and does produce pain and fever. There have been a number of such cases, I recall one in particular, that of a nurse who had acute pain and was rushed to the amphitheater and was operated on, only to find that she had a cirrhosis. Of course I shall have to agree that cirrhosis is a possibility.

CLINICAL DIAGNOSIS

Subacute hepatitis (? cirrhosis).

DR. MEANS'S DIAGNOSES

Acute infectious hepatitis (? multiple abscesses, ? cirrhosis).

Chronic bronchiectasis.

Avitaminosis (B complex).

ANATOMICAL DIAGNOSIS

Acute alcoholic hepatitis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At operation a large fatty liver was found, and biopsy showed the findings that have been described in acute alcoholic hepatitis. It was not actually a cirrhosis, because at this stage there is no actual fibrosis. The liver cells were filled with fat, and many showed the hyaline network described years ago by Dr. Frank B. Mallory.* This case showed it to an extreme degree, and around these areas there was a marked polymorphonuclear infiltration, which may have accounted for the elevated white-cell count. In the later stages of this condition there is a replacement of liver cells by connective tissue and a gradual decrease in the size of the liver to one perhaps a little larger than normal, but rarely smaller than normal.

DR. JONES: There was a real discrepancy in the history as regards the use of alcohol; I think that it is fair to say that the use of alcohol was not known to be excessive, but it may have been an important factor. Six months before entry — and this is not mentioned in the history — the patient had an episode that was clearly one of acute pellagra and that might have contributed to the development of liver disease when combined with alcohol and other unknown factors. The leukocytosis is not inconsistent with acute liver damage, even on a non-infectious basis — a point not generally recognized. I have seen a white-cell count as high as 35,000 with many immature cells, such as young myelocytes, in patients with rapidly progressing hepatic damage.

It is interesting to add that this patient has been extremely well since leaving the hospital and the liver has receded almost to the costal margin.

DR. MEANS: There was no definite history of alcoholism?

DR. MEIGS: No more than cocktail parties all last summer.

*Mallory, F. B. *The Principles of Pathologic Histology*. Philadelphia: W. B. Saunders Company, 1914. Pp. 504-508.

whether she had syphilis. There is no reason to suppose that she did. I do not believe that she had tuberculosis of the liver, but she did have a big liver. I once met my Waterloo at a clinicopathological conference in St. Louis because I had a case of big liver and jaundice and asked Dr. Chester M. Jones before I got on the train if I should consider hepatic tuberculosis. He said, "No; it is so rare that you can forget it." But it was tuberculosis of the liver.

A word or two about the acute attack. I tried to think of the various possible causes. One should always think of lymphoma, but I do not believe that lymphoma could have explained the picture.

I should like to have more than one body temperature. Was it a septic chart?

DR. CASTLEMAN: No; it was flat, the temperature reaching 99.2°F. on only one occasion.

DR. MEANS: This is really difficult — an infectious process without any fever to speak of. I still do not believe that it was cancer. Cancer of what? Of the liver, I suppose. She could not have had cancer of the lung for twelve years, that is sure. Dr. Holmes could find nothing in the lung. If the acute attack was related to the process in the lung, it must have been a process in the lung that was infectious, such as a bronchiectasis. I looked up in some textbooks to see if there was any kind of suppurative process in the lung that gives rise to suppuration in the liver. I tried to find whether a suppurative bronchopulmonary disease may extend through the diaphragm and cause diaphragmatic abscess, thus displacing the liver. We are told that it was a big displaced liver. I could not, however, find a word about that in my brief literary studies, so perhaps we cannot connect the two processes.

How about a blood-borne infection from the lung? Could a blood-borne infection get from the lung to the liver? It could through the hepatic artery, I suppose, but it seems extremely unlikely.

Let us see what we can get from the laboratory work? There were no lymphocytes in the first smear. I asked Dr. Wyman Richardson what that meant and he said that it made no sense to him; he added that it probably was a poor smear and that the examiner had counted only 100 cells. He is probably right, so that I am not going any farther with that. He also said that scarcity of lymphocytes was in favor of infection, but 3 per cent of eosinophils was against it. So there we are. They found some lymphocytes the next time though. The white-cell count was 25,000. This favors an infectious process. The nonprotein nitrogen, sugar and protein levels and the van den Bergh reaction were normal. The chloride was slightly down. The prothrombin time was only slightly elevated, but there was a positive bromsulfalein test. Would you call it an impressive dye retention, Dr. Jones?

DR. JONES: Forty per cent — yes.

DR. MEANS: So I am forced to believe that the liver was sick at least. She had a big sick liver.

What kind? Infectious, I think. How much hepatitis can one have without jaundice?

DR. JONES: A great deal.

DR. MEANS: She could have had acute cholecystitis, I suppose. That would fit this five-day story of severe pain at the right costal margin, radiating to the epigastrium but not to the back. It does not have to go into the back. One can have gall-bladder pain intermittently for twelve hours. That part of the story is all right, but with a big sick liver we must infer more than gall-bladder disease. Also, the Graham test was negative.

I thought of multiple liver abscesses in some way due to the old infection. I could not find any literary support for that hypothesis or for subdiaphragmatic abscess; but certainly there must have been something acute going on in the region of the liver, because of the acute onset of pain, the mounting white-cell count and the tenderness and spasm over the liver. I am much impressed by the last point.

That is the best that I can do. I mentioned a number of possibilities, some of which I am sure were not present. I believe that she had a chronic bronchiectasis. I believe that all the vomiting in the absence of any positive findings in the gastrointestinal tract ought to be interpreted as the result of terrific coughing. At any rate there is no positive evidence of gastrointestinal disease that permits a diagnosis, so that I shall stick to the facts and say that she had a chronic bronchopulmonary process, probably bronchiectasis of long standing. Did she have clubbed fingers?

DR. CASTLEMAN: No.

DR. MEANS: I do not believe that she had cancer, tuberculosis, actinomycosis or lymphoma. I mentioned the possibility of an amyloid liver, but that does not explain the full picture. I am therefore forced to say that she had some kind of infectious process of the liver. Where it came from I do not know. It may have been multiple abscesses. I do not believe that it could have been an amebic abscess.

DR. HOLMES: Were the sinuses examined? It is possible that the pus was coming from the sinuses instead of the lung.

DR. MEANS: A patient does not cough up a cupful of foul sputum daily and have symptoms for twelve years from a sinus.

DR. HELEN PITTMAN: Sinuses feed the bronchi.

DR. MEANS: Yes; but there has to be something in the bronchus.

DR. PITTMAN: I think that another point that Dr. Holmes brought out, namely, whether anyone saw the sputum, is a good one.

DR. MEANS: Well, of course, the whole history may be false, but I have to accept the facts given.

DR. CASTLEMAN: Dr. Meigs, will you tell us about your impression?

DR. J. V. MEIGS: This woman's acute illness necessitated a night visit. It was thought to be an

CASE 31032

PRESENTATION OF CASE

A thirty-three-year-old married woman was admitted to the hospital with malaise and diffuse distress in the lower abdomen.

One week prior to admission the patient's expected menstrual period did not appear. Instead she noted only slight staining, accompanied by a feeling of general malaise and weakness. Two days later she passed a small amount of blood per vaginam. She also noted slight soreness in the lower abdomen; this had no definite localization but gradually became more pronounced. One day prior to entry she again passed a small amount of blood. Although she felt rather "warm," there were no chills or fever. Her appetite was poor. There was no nausea, vomiting or diarrhea. She had had a normal bowel movement on the morning of admission.

The patient had been pregnant nine times and had had seven children. The last miscarriage had occurred six years before admission. Her menstrual periods were apparently regular.

Physical examination revealed a well-developed and well-nourished woman. The heart and lungs were negative. The abdomen revealed generalized tenderness with slight spasm, most marked in the right lower quadrant. Peristalsis was normal. Pelvic examination revealed a slightly enlarged uterus in anterior position; it was very tender, especially on the right. The cervix was large and lacerated, with numerous nabothian cysts. A round, firm, exquisitely tender, golf-ball-sized mass was felt posteriorly.

The temperature was 99°F., the pulse 90, and the respirations 20. The blood pressure was 120 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 11,000. The urine was negative. A laparotomy was immediately performed.

DIFFERENTIAL DIAGNOSIS

Dr. John L. Newell: This woman of child-bearing age had missed one period, and in starting to discuss the case we must first try to determine whether she was pregnant. She had amenorrhea but no history of nausea. The uterus was slightly enlarged. No mention is made of any softening of the cervix. It was too early to get a definite Hegar's sign, but there should be softening, unless it was masked by scarring subsequent to lacerations at previous childbirths. I think it is fair to assume, however, that she had an early pregnancy and that, with this irregular spotting, there was a threatened abortion. Whether the pregnancy was intrauterine or extrauterine is the next question to decide. The uterus is described as being enlarged and tender. The tenderness puzzles me somewhat because, unless

The next thing that comes to mind is the firm, — and I emphasize the word "firm," — exquisitely tender mass, about 4 cm. in diameter, in the pouch of Douglas. If she had an extrauterine pregnancy and had had an incomplete tubal abortion, having pushed the ovum into the peritoneal cavity, the mass should not be that large, and at this stage of pregnancy it should not be so firm as described. I shall return to that later.

Dr. Newell: I do not remember seeing either an intrauterine or an extrauterine abortion in which the uterus itself was tender. Tenderness in the right vault is to be expected if it was an extrauterine pregnancy.

Dr. Benjamin Castleman: The note says that the uterus was "very tender."

I cannot interpret it. What is meant I believe is that manipulation of the uterus, rather than bi-manual pressure on the uterus itself, caused pain.

Dr. Benjamin Castleman: The note says that the uterus was "very tender."

Dr. Fred A. Simmons, Jr.: According to our experience in the Emergency Ward, the presence of a mass in the pelvis that is exquisitely tender is definite evidence of tubal pregnancy. I believe that this patient did have a tubal pregnancy.

Dr. Edward Hamlin, Jr.: Would it not be unusual for the mass to be described as round, firm and golf-ball-sized? The description alone, if it is accurate, argues against tubal pregnancy; such a mass is usually indefinite with the amount of pressure that one can use and is seldom firm.

Dr. Newell: This ovum was only three weeks of age. If it had been aborted into the pouch of Douglas, the mass might be as large as a golf ball because of surrounding blood clot, but it should not be firm and hard.

Dr. Francis M. Ingersoll: I agree that it seems much more like a cyst that had twisted than a tubal pregnancy; she may have had an intrauterine pregnancy that was ready to abort.

CLINICAL DIAGNOSIS

Tubal pregnancy.

Dr. Newell's Diagnosis

Cyst of right ovary, with torsion.
Probable intrauterine pregnancy.

CASE 31032

PRESENTATION OF CASE

A thirty-three-year-old married woman was admitted to the hospital with malaise and diffuse distress in the lower abdomen.

One week prior to admission the patient's expected menstrual period did not appear. Instead she noted only slight staining, accompanied by a feeling of general malaise and weakness. Two days later she passed a small amount of blood per vaginam. She also noted slight soreness in the lower abdomen; this had no definite localization but gradually became more pronounced. One day prior to entry she again passed a small amount of blood. Although she felt rather "warm," there were no chills or fever. Her appetite was poor. There was no nausea, vomiting or diarrhea. She had had a normal bowel movement on the morning of admission.

The patient had been pregnant nine times and had had seven children. The last miscarriage had occurred six years before admission. Her menstrual periods were apparently regular.

Physical examination revealed a well-developed and well-nourished woman. The heart and lungs were negative. The abdomen revealed generalized tenderness with slight spasm, most marked in the right lower quadrant. Peristalsis was normal. Pelvic examination revealed a slightly enlarged uterus in anterior position; it was very tender, especially on the right. The cervix was large and lacerated, with numerous nabothian cysts. A round, firm, exquisitely tender, golf-ball-sized mass was felt posteriorly.

The temperature was 99°F., the pulse 90, and the respirations 20. The blood pressure was 120 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 11,000. The urine was negative.

A laparotomy was immediately performed.

DIFFERENTIAL DIAGNOSIS

DR. JOHN L. NEWELL: This woman of child-bearing age had missed one period, and in starting to discuss the case we must first try to determine whether she was pregnant. She had amenorrhea but no history of nausea. The uterus was slightly enlarged. No mention is made of any softening of the cervix. It was too early to get a definite Hegar's sign, but there should be softening, unless it was masked by scarring subsequent to lacerations at previous childbirths. I think it is fair to assume, however, that she had an early pregnancy and that, with this irregular spotting, there was a threatened abortion. Whether the pregnancy was intrauterine or extrauterine is the next question to decide. The uterus is described as being enlarged and tender. The tenderness puzzles me somewhat because, unless

there had been an attempt at a criminal abortion, I cannot interpret it. What is meant I believe is that manipulation of the uterus, rather than manual pressure on the uterus itself, caused pain.

DR. BENJAMIN CASTLEMAN: The note says that the uterus was "very tender."

DR. NEWELL: I do not remember seeing either an intrauterine or an extrauterine abortion in which the uterus itself was tender. Tenderness in the right vault is to be expected if it was an extrauterine pregnancy.

The next thing that comes to mind is the firm, — and I emphasize the word "firm," — exquisitely tender mass, about 4 cm. in diameter, in the pouch of Douglas. If she had an extrauterine pregnancy and had had an incomplete tubal abortion, having pushed the ovum into the peritoneal cavity, the mass should not be that large, and at this stage of pregnancy it should not be so firm as described. I shall return to that later.

The abdominal findings are interesting. She had a history of pain, which became severer over a period of days. She had also tenderness, chiefly localized in the right lower quadrant. This, of course, is consistent with an incomplete tubal abortion, and that is also true for the temperature, pulse, blood pressure and leukocytosis. The main point in my mind against an ectopic pregnancy is this mass. I believe that she had a twisted cyst of the right ovary. Whether the cause of the abortion was the fact that the corpus luteum happened to be in the right ovary, I do not know; that would be a perfectly logical conclusion.

DR. FRED A. SIMMONS, JR.: According to our experience in the Emergency Ward, the presence of a mass in the pelvis that is exquisitely tender is definite evidence of tubal pregnancy. I believe that this patient did have a tubal pregnancy.

DR. EDWARD HAMLIN, JR.: Would it not be unusual for the mass to be described as round, firm and golf-ball-sized? The description alone, if it is accurate, argues against tubal pregnancy; such a mass is usually indefinite with the amount of pressure that one can use and is seldom firm.

DR. NEWELL: This ovum was only three weeks of age. If it had been aborted into the pouch of Douglas, the mass might be as large as a golf ball because of surrounding blood clot, but it should not be firm and hard.

DR. FRANCIS M. INGERSOLL: I agree that it seems much more like a cyst that had twisted than a tubal pregnancy; she may have had an intrauterine pregnancy that was ready to abort.

CLINICAL DIAGNOSIS

Tubal pregnancy.

DR. NEWELL'S DIAGNOSES

Cyst of right ovary, with torsion.
Probable intrauterine pregnancy.

ANATOMICAL DIAGNOSIS

Acute salpingo-oöphoritis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: I am sorry that the surgeon who operated on this patient is not here. At operation he found a slightly enlarged uterus; the right tube was thick, red and reflected on itself, so that the fimbriated end lay in the posterior cul-de-sac and was held there by adhesions. The left tube was also slightly reddened but normal in size and shape. The right ovary was moderately enlarged, firm and intimately connected with the enlarged right tube. The tube and ovary were removed.

The preoperative and postoperative diagnoses were ectopic pregnancy, but microscopic examination showed no evidence of pregnancy. The tube was markedly edematous and filled with pus. It was one of the most acutely inflamed tubes that we have seen for a long time, but of course they are usually not removed in the acute stage. There was

acute inflammatory disease of the pelvis, which had involved the right tube and ovary and, to a lesser degree, the left tube. There was probably also an acute endometritis, which perhaps accounted for the slight increase in the size of the uterus.

DR. SIMMONS: Was she pregnant?

DR. CASTLEMAN: No; a Friedman test done after operation was negative, which ruled out an intra-uterine pregnancy. I do not believe that pregnancy could have occurred in the presence of such a pyosalpinx.

DR. SIMMONS: Is it not true that you frequently receive specimens from patients who clinically have proved tubal pregnancies in which you do not find decidua or villi?

DR. CASTLEMAN: In such cases the tubes are filled with blood and there is no acute infection in the wall of the tube. In this case there was inflammation in the wall of the tube, frank pus within it, and fibrin on its surface. There is no doubt about the diagnosis.

CASE 31032

PRESENTATION OF CASE

A thirty-three-year-old married woman was admitted to the hospital with malaise and diffuse distress in the lower abdomen.

One week prior to admission the patient's expected menstrual period did not appear. Instead she noted only slight staining, accompanied by a feeling of general malaise and weakness. Two days later she passed a small amount of blood per vaginam. She also noted slight soreness in the lower abdomen; this had no definite localization but gradually became more pronounced. One day prior to entry she again passed a small amount of blood. Although she felt rather "warm," there were no chills or fever. Her appetite was poor. There was no nausea, vomiting or diarrhea. She had had a normal bowel movement on the morning of admission.

The patient had been pregnant nine times and had had seven children. The last miscarriage had occurred six years before admission. Her menstrual periods were apparently regular.

Physical examination revealed a well-developed and well-nourished woman. The heart and lungs were negative. The abdomen revealed generalized tenderness with slight spasm, most marked in the right lower quadrant. Peristalsis was normal. Pelvic examination revealed a slightly enlarged uterus in anterior position; it was very tender, especially on the right. The cervix was large and lacerated, with numerous nabothian cysts. A round, firm, exquisitely tender, golf-ball-sized mass was felt posteriorly.

The temperature was 99°F., the pulse 90, and the respirations 20. The blood pressure was 120 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 11,000. The urine was negative.

A laparotomy was immediately performed.

DIFFERENTIAL DIAGNOSIS

DR. JOHN L. NEWELL: This woman of child-bearing age had missed one period, and in starting to discuss the case we must first try to determine whether she was pregnant. She had amenorrhea but no history of nausea. The uterus was slightly enlarged. No mention is made of any softening of the cervix. It was too early to get a definite Hegar's sign, but there should be softening, unless it was masked by scarring subsequent to lacerations at previous childbirths. I think it is fair to assume, however, that she had an early pregnancy and that, with this irregular spotting, there was a threatened abortion. Whether the pregnancy was intrauterine or extrauterine is the next question to decide. The uterus is described as being enlarged and tender. The tenderness puzzles me somewhat because, unless

there had been an attempt at a criminal abortion, I cannot interpret it. What is meant I believe is that manipulation of the uterus, rather than bimanual pressure on the uterus itself, caused pain.

DR. BENJAMIN CASTLEMAN: The note says that the uterus was "very tender."

DR. NEWELL: I do not remember seeing either an intrauterine or an extrauterine abortion in which the uterus itself was tender. Tenderness in the right vault is to be expected if it was an extrauterine pregnancy.

The next thing that comes to mind is the firm, — and I emphasize the word "firm," — exquisitely tender mass, about 4 cm. in diameter, in the pouch of Douglas. If she had an extrauterine pregnancy and had had an incomplete tubal abortion, having pushed the ovum into the peritoneal cavity, the mass should not be that large, and at this stage of pregnancy it should not be so firm as described. I shall return to that later.

The abdominal findings are interesting. She had a history of pain, which became severer over a period of days. She had also tenderness, chiefly localized in the right lower quadrant. This, of course, is consistent with an incomplete tubal abortion, and that is also true for the temperature, pulse, blood pressure and leukocytosis. The main point in my mind against an ectopic pregnancy is this mass. I believe that she had a twisted cyst of the right ovary. Whether the cause of the abortion was the fact that the corpus luteum happened to be in the right ovary, I do not know; that would be a perfectly logical conclusion.

DR. FRED A. SIMMONS, JR.: According to our experience in the Emergency Ward, the presence of a mass in the pelvis that is exquisitely tender is definite evidence of tubal pregnancy. I believe that this patient did have a tubal pregnancy.

DR. EDWARD HAMLIN, JR.: Would it not be unusual for the mass to be described as round, firm and golf-ball-sized? The description alone, if it is accurate, argues against tubal pregnancy; such a mass is usually indefinite with the amount of pressure that one can use and is seldom firm.

DR. NEWELL: This ovum was only three weeks of age. If it had been aborted into the pouch of Douglas, the mass might be as large as a golf ball because of surrounding blood clot, but it should not be firm and hard.

DR. FRANCIS M. INGERSOLL: I agree that it seems much more like a cyst that had twisted than a tubal pregnancy; she may have had an intrauterine pregnancy that was ready to abort.

CLINICAL DIAGNOSIS

Tubal pregnancy.

DR. NEWELL'S DIAGNOSES

Cyst of right ovary, with torsion.
Probable intrauterine pregnancy.

V. D.

THE war against V. D. is going well. Turner¹ in reporting on the control of these diseases since 1940 points out that the yearly time lost from these infections in the United States Army has been reduced from 1278 days per 1000 men in 1940 to 368 days in 1943. The Army data also show that the V. D. morbidity rate is below the preceding peace level and half that of World War I.² In civilian life a review of the figures for all states for 1943-1944 shows 100,000 fewer cases of syphilis than previously; in only thirteen states were there more cases than before, and in most of these states the increase was slight.³

Much credit for these excellent results among military personnel must be given to the appointment of V. D. C. (venereal-disease-control) officers in the Army and in the United States Public Health Service. Their conscientious efforts at various stations deserve every commendation that can be bestowed. Much has been attained by applying the principles of preventive medicine to these diseases. Such a program has been well outlined in a recent number of *Lancet* by Gordon.⁴ It is to be hoped that this program can be carried over into civilian life in the postwar period.

These V. D. C. officers have also had the advantage of the apparently improved therapeutic measures that have been developed in the last four or five years. The progress report in this issue of the *Journal* reviews these new methods of treatment—the use of penicillin and the sulfonamides, the intensive use of arsenicals and their combination with fever therapy and so forth. This report also strongly emphasizes the need for caution in universally adopting these procedures until they have been found to be safe and have been proved to produce, in the long run, as good or better end results than the present-day accepted methods of treatment have accomplished.

Many other matters in connection with these diseases need further thought and discussion. The matter of juvenile delinquency has been found to be tied closely to this problem, and every agency should be mobilized to aid in the solution of reaching the family and the small community. Educa-

tion of the civilian population in matters pertaining to these diseases has been stressed and much has been done, but further effort is needed. Demobilization will bring its problems. Will the venereally infected veteran be discharged before cure to carry the infection back to civilians, or will he be held and paid as a soldier until cured? Will the experience of the V. D. C. officers in this field be put to use in civilian life to lessen further the incidence of these diseases? Time only can answer these and other questions.

With the epidemiologic principles set forth by Gordon and the experience gained in the war, with adequate regulations and their enforcement regarding contagious disease and with the rational use of the new therapeutic procedures, the demobilized V. D. C. officer can contribute greatly to a further decrease in the incidence of venereal disease.

MASSACHUSETTS MEDICAL SOCIETY
STATED MEETING OF THE COUNCIL

A stated meeting of the Council of the Massachusetts Medical Society will be held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, February 7, 1945, at 10:30 a.m.

Business:

1. Call to order at 10:30 a.m.
2. Presentation of record of meeting held October 4, 1944, as published in *The New England Journal of Medicine*, issue of December 21, 1944.
3. Reports of standing and special committees.
4. Appointment of delegates:
 - (a) To the House of Delegates, American Medical Association, for two years from June 1, 1945.
 - (b) To the annual meetings of the five New England state medical societies in 1945.
 - (c) To the Annual Congress of the American Medical Association on Medical Education and Licensure at the Palmer House, Chicago, February 12 and 13, 1945.
5. Such other business as may lawfully come before this meeting.

MICHAEL A. TIGHE, M.D., *Secretary*

DEATHS

MAHONEY—John L. Mahoney, M.D., formerly of Boston, died January 2 at St. Petersburg, Florida. He was in his seventy-third year.
Dr. Mahoney received his degree from Boston University School of Medicine in 1898.

WIGGIN — William I. Wiggin, M.D., of Lowell, died January 3. He was in his sixty-sixth year.

Dr. Wiggin received his degree from McGill University Medical School in 1901. During World War I he served overseas for eighteen months with a Red Cross field unit. He taught otolaryngology at Harvard Medical School from 1919 until his retirement a few years ago. During the same period he served as staff surgeon at the Massachusetts Eye and Ear Infirmary. He had also been a member of the Lowell General Hospital staff for many years. He was a fellow of the American College of Surgeons and the American Medical Association, and a member of the American Board of Otolaryngology, the American Academy of Ophthalmology and Otolaryngology, and the New England Otological and Laryngological Society. At the time of his death, he was vice-president of the Middlesex North District Medical Society.

His widow and his mother survive.

CORRESPONDENCE

TREATMENT OF THE COMMON COLD

To the Editor: In the April, 1944, issue of the *Journal of the Maine Medical Association* there appeared an article by me which was a review of outstanding work pertaining to the common cold. The review was made because of the fact that a number of patients had divulged that they had received "cold serums" and other useless forms of medication that, on the whole, seemed to be perhaps more harmful than good.

The onset of the common cold — the virus stage — is characterized by sneezing, watery discharge and stuffiness of the nose, with a subnormal or normal temperature. Influenza, on the other hand, has a sudden onset with fever, headache and neuromuscular or gastrointestinal manifestations.

During the virus stage of the common cold, which lasts for three or four days, immediate and proper treatment can abort the secondary phase of this ailment.

One must avoid drying, mentholated, creamy or oily nose medication, cathartics and alcohol. Equally useless, in my mind, are the vitamins (in the otherwise healthy person), sulfonamides, soda, aspirin, calcium and iodine, liver oil, amyral, ephedrine, atropine, quinine and like drugs.

The crux of the treatment for the virus phase of the common cold is in the intelligent use of the hot bath and medication with the opium derivatives, codeine and papaverine. Such treatment has never failed to abort the first stage of the common cold in any of my patients who followed directions explicitly.

Copavin, which is a commercial preparation containing $\frac{3}{4}$ gr. each of codeine and papaverine, is given, the dosage being one tablet (or capsule) after meals and two at bedtime or one tablet every three hours and two at bedtime. The dosage is regulated according to the severity of the symptoms and to the size of the patient. If the symptoms are severe, two tablets may be given for the first and second doses and three at bedtime. For children the dosage is, of course, regulated according to size. The codeine-papaverine combination was conceived by Diehl and his co-workers, who observed that chronic users of opium and its derivatives were remarkably free from the common cold.

The hot-bath regime must be explained to the patient. The tub should be half full of hot water, and the body should be kept well immersed until perspiration occurs on the head (debilitated patients should not, of course, be submitted to this). From the bath the patient goes immediately to a warmed bed and remains there two or three hours in a well-aired room.

If this treatment is performed during the early stage of the common cold the secondary stage, with its week or two of distress, can be entirely eliminated.

BOOK REVIEWS

The Romance of Medicine: The story of the evolution of medicine from occult practices and primitive times. By Benjamin L. Gordon, M.D. 8° cloth, 624 pp., with 145 illustrations. Philadelphia: F. A. Davis Company, 1944. \$5.00.

This volume is not a history of medicine in the conventional biographic pattern; rather, it is a series of philosophic essays on the evolution of medicine from the standpoint of a number of its principal problems in primitive time — animism, reproduction, heredity, physiology, disease, demonology, witchcraft, hysteria, the evil eye, astrology, symbolism, superstition, scapegoatism, signature, biologic products, hydrotherapy, psychotherapy, medical ethics and immortality. Under each of these subjects the author surveys the field from prehistoric to modern time, with a wealth of scholarly allusion, quotation and reference. Everything in modern medicine has derived, often in devious ways, from the earliest past. That is what to him constitutes its romance.

The book contains excellent illustrations, many of which are unfamiliar. The footnotes, which afford a compendium of strange information and references in addition to those of the text, are extremely valuable.

The more one contemplates the eccentricities of the past, the less one wonders at those of the present. No book is quite like this, unless it be Dr. Howard W. Haggard's *Devils, Drugs and Doctors* of fifteen years ago. Dr. Gordon's essays are wider-ranging, but all are from the same point of view. It is unfortunate that so excellent a work is marred by so many obvious misprints; the book is, nevertheless, a worthy achievement of scholarship.

The Dental Treatment of Maxillo-Facial Injuries: With supplementary material on cases and techniques. By W. Kelsey Fry, M.C., M.R.C.S., L.R.C.P., L.D.S., R.C.S. (Eng.), P. Rae Shepherd, L.D.S., R.C.S. (Eng.), Alan C. McLeod, D.D.S. (Penn.), B.Sc. (dent., Toronto), L.D.S., R.C.S. (Eng.), and Gilbert J. Parfitt, M.R.C.S., L.R.C.P., L.D.S., R.C.S. (Eng.). With foreword by Professor F. R. Fraser, M.D., F.R.C.P., and a section on fractures of the middle third of the face by A. H. McIndoe, M.S., F.R.C.S., F.A.C.S. 8°, cloth, 434 pp., illustrated. Philadelphia: J. B. Lippincott Company, 1944. \$6.50.

The surgical treatment of wounds has made great progress in the last thirty years. This branch of surgery began in World War I, but progress slowed down between 1918 and 1939. In the present war it is, of necessity, again progressing and has made its greatest advance in the field of facial injuries.

Fry and his colleagues have presented the knowledge accumulated during the last thirty years with clarity and intelligence. This book originally appeared in England and was published in two separate volumes, but the American publishers have wisely combined the material into a single volume.

The first half of the book presents all phases of maxillo-facial injury, including the treatment of soft-tissue injuries as well as bony injuries, with detailed descriptions of the methods of fixation, all illustrated with excellent photographs and diagrams.

The second half of the book is chiefly devoted to case studies and technic. The outstanding chapters in this section are those on pathology and surgery, illustrated with colored photomicrographs. There is also a chapter on fractures of the middle third of the face, which includes fractures of the maxillary, nasal and malar bones. Several case histories are presented, each with remarks and an analysis of the method of treatment employed.

The title suggests that this book deals primarily with the dental treatment of facial injuries, that is, with the treatment by dental surgeons. This inference is partly true, but the book also presents instructive chapters for plastic and general surgeons who may be called to treat facial injuries.

In reading this book one is impressed with the central idea: in treating maxillofacial injuries, especially in combat areas, there must be intelligent co-operation and co-ordination by the dental and the plastic surgeons. Emphasis is also placed on the importance of specialized centers for the treatment of these casualties, where the teamwork that is essential for the best results can be obtained.

Emphasis is also placed on the importance of specialized centers for the treatment of these casualties, where the teamwork that is essential for the best results can be achieved.

Technique in Trauma: Planned timing in the treatment of wounds including burns. From the Montreal General Hospital and McGill University. By Fraser B. Gurd, M.D., C.M.; and F. Douglas Ackman, M.D., C.M. In collaboration with John W. Gerrie, M.D., C.M., Edward S. Mills, M.D., C.M., Joseph E. Pritchard, M.D., and Frederick Smith, M.D. Preface by John S. Lockwood, M.D. With commentary by Ralph R. Fitzgerald, M.D., C.M. 4^o, cloth, 68 pp., with 3 plates, 17 figures, 5 tables and 3 charts. Philadelphia: J. B. Lippincott Company, 1944. \$2.00.

This book consists of three papers published within the last two years, together with an introduction and a commentary that represent new material. These papers outline the detailed directions now being used in the Montreal General Hospital, treatment being based on the use of the most advanced and modern concepts that are now current in the surgical world. They therefore make available to the practitioner and student, in easily assimilable form, methods of treatment that have been safely and successfully used. Anyone who is occasionally or frequently confronted with decisions in the care of serious burns, extensive soft-part injuries or compound fractures can well afford to buy and give careful thought to the contents of this book.

Above all, it stresses that no individual can give adequate treatment to these cases but that carefully trained teams are necessary. This has been a universal experience in the last few years, but the organization of the necessary teamwork has seldom been discussed.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Infants without Families: The case for and against residential nurseries. By Anna Freud; and Dorothy Burlingham. 12^o, cloth, 128 pp. New York: International University Press, 1944. \$2.00.

This monograph deals with the care of homeless and parentless children, made so by the exigencies of war. It is based on the authors' experience at the Hempstead Nurseries in England. An attempt has been made to evaluate the advantages and disadvantages of institutional life at different phases of the infant's development. The text is divided into a number of chapters having to do with the aspects of development between birth and two years, early relations between institutional infants, introduction of the mother-relation into the nursery life, some aspects of instinctual satisfaction and frustration in family and nursery life, the role of the father in the residential nursery and the growth of the child's personality under nursery conditions. The authors conclude that institutional nurseries offer excellent opportunities for detailed and unbroken observation of child development but agree that the continuance of such nurseries after the war will be decided probably by social and economic needs and not on the basis of psychological requirements. The primary objective of the book is to discuss the questions: Should residential nurseries be maintained and, if so, can they be changed so as not to produce the so-called "institutional child"?

Man Does Not Stand Alone. By A. Cressy Morrison. 12^o, cloth, 107 pp. New York: Fleming H. Revell Company, 1944. \$1.25.

This small book attempts a review of the scientific evidence of the existence of a supreme intelligence and is written as a challenge to Julian Huxley's *Man Stands Alone*, in which Mr. Huxley states that he does not believe in God or gods.

Bailey's Textbook of Histology. Revised by Philip E. Smith, Ph.D., professor of anatomy, College of Physicians and Surgeons, Columbia University; and Wilfred M. Copenhaver, Ph.D., associate professor of anatomy, College of Physicians and Surgeons, Columbia University. With the assistance of

Aura E. Severinghaus, Ph.D., associate professor of anatomy, College of Physicians and Surgeons, Columbia University; and Charles M. Goss, M.D., professor of anatomy, University of Alabama Medical School. Eleventh edition. 8^o, cloth, 786 pp., with 470 illustrations. Baltimore: The Williams and Wilkins Company, 1944. \$6.00.

This edition of an authoritative teaching text, first published in 1904, has been thoroughly revised. The primary objective of providing a text for first-year medical students has been adhered to as in previous editions. The chapter on the female reproductive system has been amplified by the addition of a section on the placenta. The text throughout the book has been brought up to date and in places has been extended or clarified. Many new figures in color and halftone have been introduced throughout the book. Lists of carefully selected bibliographic references are appended to each chapter.

Heart Disease. By Paul D. White, M.D., lecturer in medicine, Harvard Medical School, and physician, Massachusetts General Hospital, Boston. Third edition, completely revised and reset. 8^o, cloth, 1025 pp., with 138 illustrations. New York: The Macmillan Company, 1944. \$9.00.

This standard treatise has been thoroughly revised and brought up to date. An important addition is a chapter on the range of the normal heart. New material added includes phonocardiography, precordial leads, ligation of the patent ductus arteriosus, treatment of subacute bacterial endocarditis, splachnic resection for hypertension, intracardiac thrombosis, pulmonary embolism and the heart in gastrointestinal diseases. There is also a new section on heart disease in military service. Many of the historical references that appeared in the first edition and were omitted in the second have now been replaced, owing to a demand from the readers of the book. New references to articles of importance appearing during 1937-1943 have been added after each chapter, whereas many of the references of current interest in the years 1931-1936 have been omitted. In order to obtain a complete bibliography one must consult the editions of 1931 and 1937. A number of illustrations have been added to the text.

Fundamentals of Internal Medicine. By Wallace M. Yater, M.D., M.S. (med.), professor of medicine and director of the Department of Medicine, Georgetown University School of Medicine, physician-in-chief, Georgetown University Hospital, and physician-in-chief, Gallinger Municipal Hospital, Washington, D. C. Second edition. 8^o, cloth, 1204 pp., with 275 illustrations. New York: D. Appleton-Century Company, Incorporated, 1944. \$10.00.

The second edition of this book has been revised to conform to war conditions. New material of interest to the military internist has been added, including medical problems incidental to flying, immersion foot, blast injuries, effects of chemical warfare, war neuroses and tropical medicine. Many other subjects have been added or revised, including blood-typing, liver-function tests and a preliminary evaluation of penicillin. Three new sections have been written entitled "Symptomatic and Supportive Treatment," "Clinical Values and Useful Tables" and "The Physician Himself." A more comprehensive index has been made, and additional illustrations have been inserted in the text. The objective of this book is to include in one volume all the clinical subjects that an internist may encounter in his daily work.

The Electrocardiogram: Its interpretation and clinical application. By Louis H. Sigler, M.D., attending cardiologist and chief of the Cardiac Clinic, Coney Island and Harbor hospitals, New York. 8^o, cloth, 403 pp., with 203 illustrations. New York: Grune and Stratton, Incorporated, 1944. \$7.50.

The objective of this book is to present in a simple but comprehensive manner all that relates to the electrocardiogram and its practical application to cardiology. The work is well illustrated with figures comprising nearly four hundred electrocardiograms. The book is divided into twenty-five chapters beginning with the biological and physical foundations of the electrocardiograph, its recording and the classification of electrocardiograms, followed by chapters on the various cardiac disorders.

Rehabilitation, Re-education and Remedial Exercises. By Olive F. Guthrie Smith, M.B.E., C.S.M.M.G., T.M.G., principal of the Swedish Institute, London, and director of

the Physical Exercise Department, St. Mary's Hospital. With a foreword by Lord Horder, G.C.V.O., M.D., F.R.C.P. 8°, cloth, 424 pp., with 273 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$6.00.

This book is devoted primarily to a discussion of remedial exercises in various orthopedic conditions, with emphasis on the suspension methods of the author.

X-Ray Examination of the Stomach: A description of the roentgenologic anatomy, physiology and pathology of the esophagus, stomach and duodenum. By Frederic E. Templeton, M.D., head of the Department of Roentgenology, The Cleveland Clinic. 8°, cloth, 516 pp., with 297 illustrations. Chicago: The University of Chicago Press, 1944. \$10.00.

This monograph is devoted to an intensive study of the upper digestive tract by the x-ray. It includes a presentation of modern, roentgenologic methods and their use and interpretation, together with the detailed consideration of the normal and abnormal manifestations encountered in the stomach, esophagus and duodenum, with careful, differential diagnosis. The filming fluoroscope is described and discussed. The work is well illustrated and printed on heavy paper in a legible type.

Insulin Shock Therapy. 8°, paper, 97 pp., with 13 tables. New York: Temporary Commission on State Hospital Problems, 1944. Available, without cost, on application.

The commission recommends that insulin-shock therapy for dementia praecox be made available in all the state hospitals for the insane in New York. The recommendation is based on the results of an intensive study of 1128 dementia-praecox patients treated with insulin shock at the Brooklyn State Hospital in five and a half years and a comparable group of 876 patients admitted to the state hospitals in the metropolitan area who did not receive that form of treatment. The commission found that insulin-treated patients did better in all respects than a group not so treated. More patients left the hospital after a shorter stay, and a larger number were living usefully at home. It was also found that over half the institutional population of mental hospitals was made up of dementia-praecox cases. The reports showed great direct savings in hospital days and in the cost of food and clothing and undetermined indirect savings in maintenance costs and ultimately in construction costs. The commission was appointed in November, 1940, and made a progress report in November, 1942, at which time it recommended the extension of shock therapy, as well as increasing the number of patients placed on parole or in family care. It stated that increased effort in these directions had not only halted the rate of increase of patients in state hospitals but that during a four-month period in 1942 the long-standing average increase of about 2400 patients had given place to a decrease of 78. This was the first such reversal in fifty years of state care of the insane. The commission concludes that insulin-shock therapy produces substantially better results in the treatment of dementia praecox than those obtained when insulin is not administered. What is more striking, good results were obtained even in those cases in which the prognosis without insulin is usually doubtful, such as patients in the older age groups, those whose illnesses have a duration of more than a year and those with a gradual onset.

New and Nonofficial Remedies, 1944. Issued under the direction and supervision of the Council on Pharmacy and Chemistry, American Medical Association. 12°, cloth, 778 pp. Chicago: American Medical Association, 1944. \$1.50.

The current volume of *New and Nonofficial Remedies* reflects two important and forward-looking decisions of the Council, namely, to use the metric system exclusively in all its publications and to consider for acceptance contraceptive preparations offered for use as prescribed by physicians.

The chapter on contraceptives is quite comprehensive, and the Council has thus far accepted certain contraceptive jellies and creams, diaphragms, diaphragm inserts, syringe applicators and fitting rings.

A number of new preparations are described. Certain general articles have been revised to bring them up to date, and more or less important revisions have been made in other chapters.

Surgical Disorders of the Chest: Diagnosis and treatment. By J. K. Donaldson, M.D., associate professor of surgery and in charge of thoracic surgery, University of Arkansas School of Medicine, and member of surgical staff, St. Vincent's Infirmary, and visiting staff, Baptist Hospital, Little Rock, Arkansas. 8°, cloth, 364 pp., with 127 illustrations. Philadelphia: Lea and Febiger, 1944. \$6.50.

This new work on thoracic surgery has been written primarily for general practitioners, general surgeons and students. It contains in a simple form the advances made in the field of chest surgery during the past decade. In line with this objective, controversial discussions, long statistical and historical reviews, unnecessary detail and long bibliographies have been omitted. Some discussion pertaining to war injuries has been included, although the author believes that the fundamental problems, with a few exceptions, are the same in both war and civilian injuries of the chest.

The Art of Anaesthesia. By Paluel J. Flagg, M.D., visiting anesthetist to Manhattan Eye and Ear Hospital, consulting anesthetist to St. Vincent's Hospital, New York, consulting anesthetist to the Woman's Hospital, Sea View Hospital, Jamaica Hospital, Mount Vernon Hospital, Flushing Hospital, Mary Immaculate Hospital, St. Mary's Hospital (Far Rockaway) and Nassau Hospital, Long Island. Seventh edition. 8°, cloth, 517 pp., with 166 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$6.00.

Five years have elapsed since the sixth edition of this standard text was published. During this period much progress has been made in the field of anesthesia. This edition discusses thoroughly the pros and cons of military anesthesia, as well as the newer developments in the field of anesthesia.

The Gastro-Intestinal Tract: A handbook of roentgen diagnosis. By Fred J. Hodges, M.D., professor of roentgenology, University of Michigan Medical School. 8°, cloth, 320 pp., with 130 plates. Chicago: The Year Book Publishers, Incorporated, 1944. \$5.50.

This manual consists of a large number of reproductions of x-ray films, with running descriptions of each.

The Analysis and Interpretation of Symptoms. Edited by Cyril M. MacBryde, M.D. 8°, cloth, 301 pp., illustrated. Philadelphia: J. B. Lippincott Company, 1944. \$9.00.

This symposium by ten specialists gives the basis for analysis and interpretation of some of the common symptoms found in patients. Emphasis is placed on the pathologic physiology of symptoms, whereas their correlation with other symptoms and with physical and laboratory evidence is considered as important but secondary in the diagnostic method.

NOTICES

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held on Monday, January 29, at 8:15 p.m., at the Boston Medical Library.

PROGRAM

Echinococcal Heart Disease. Drs. Lewis Dexter and John Peters.

Some Clinical Effects of Cytochrome C in Anoxia. Drs. Samuel Proger, D. Decaneas and Gerhardt Schmidt.

Studies on Experimental Pulmonary Edema. Drs. A. A. Luisada and S. J. Sarnoff.

Insomnia Due to Unrecognized Left Ventricular Failure. Drs. Edwin Wheeler, Conger Williams, and Paul D. White.

Interested physicians and medical students are cordially invited to attend.

THE WATERHOUSE-FRIDERICHSEN SYNDROME*

Report of a Case With Recovery

LEONARD D. WEINBERG, M.D.,† AND THOMAS HODGE MCGAVACK, M.D.‡

NEW YORK CITY

THE symptom complex known as the Waterhouse-Friderichsen syndrome was first described by Voelcker¹ in 1894. Early in 1944, Haas² found 144 cases reported in the literature, to which he added 3 of his own. Rucks and Hobson³ stated that up to the beginning of 1942 there were 101 recorded cases, 26 of which had been reported in the preceding three years. Assuming that these workers did not overlook any cases up to the time of their respective communications, it appears that approximately 75 cases of the syndrome were reported between 1894 and 1939 and 75 in the five years from 1939 to 1943, inclusive. Since that time, Bernhard and Jordan⁴ have reported 4 cases, Bush and Bailey⁵ 6, and Meyer,⁶ Martland⁷ and Short and his associates⁸ each 1, bringing the present total to 157. This suggests not so much an increased incidence as an increased interest in the disease and an improvement in methods for its recognition and treatment. Several excellent reviews and summaries have recently appeared,^{2-5,9,10} but little has been said concerning the treatment, since the prognosis was hopeless prior to the advent of the sulfonamide drugs and potent adrenocortical preparations. Thus far, recovery has been reported in 11 patients.^{5,11-16} Significant data, particularly in regard to treatment, from these cases and the one presented below are summarized in Table 1:

Of the 11 cases of Waterhouse-Friderichsen syndrome in which recovery has been reported, 3 were not described in sufficient detail to permit critical analysis,^{13,15} but there seems to be little room for doubt about the diagnosis in any of them. Several features of special interest deserve to be emphasized.

Age Incidence

The Waterhouse-Friderichsen syndrome has been seen predominantly in children, Lindsay and his

co-workers¹⁷ noting that 90 per cent of the patients were under nine years of age. On the other hand, of those who have recovered to date, only 1 was under the age of nine. In this case, the skin lesions were apparently much severer and the toxemia greater than in the other 10 patients. The recent increase in cases reported may be due to the high incidence in Army camps. Although the age incidence is of somewhat less importance from a statistical viewpoint since the number of cases is so small, mere coincidence hardly accounts for recovery in 11 adults and in only 1 child. Significance may also attach to the fact that the child ran the stormiest course of all and developed the severest skin manifestations, with large necrotic lesions. This is compatible with the general principle that children react in a more labile fashion than do adults and exhibit much profounder reactions to identical stimuli. The present patient, sixty-three years of age, is the oldest on record with recovery, and the only one in whom a preceding hypertension was known to have existed.

Etiology

In the earlier reports, a meningococcemia was postulated as the causative factor of the disturbance. At present, the etiology of the condition is far from settled. The meningococcus was cultured from the blood stream of 6 of the 12 patients who survived, *Staphylococcus aureus* from 1, and a pneumococcus from 1. One patient had a negative blood culture. In 3 cases there was no record of a study of the blood for organisms, but 2 of these showed organisms in the spinal fluid (Table 1).

The pathologic changes may be explained anatomically.³ The frequency with which the meningococcus has been recovered from blood and spinal fluid has supported the concept of an organismal ectodermal tropism, in which the skin, adrenal glands and brain are simultaneously involved.¹⁸ Cerebral changes have been demonstrated histologically.¹⁹

*From the Department of Medicine, New York Medical College, and the Medical Service of the Metropolitan Hospital.

†Formerly, resident in medicine, Metropolitan Hospital.

‡Associate professor of medicine, New York Medical College; visiting physician, Flower-Fifth Avenue and Metropolitan hospitals.

Morbidity

The rapidity with which reports have been appearing in the recent literature suggests that the Waterhouse-Friderichsen syndrome occurs much more frequently than was formerly thought. The average incidence in the last 485 cases of meningitis reported from Army camps^{4-6,20} was 3.3 per cent; it occurred in 4 of 182 patients,⁴ 5 of 134,²⁰ 6 of 126,⁵ and 1 of 43.⁶

Treatment

Sulfonamides were used in the treatment of each of the 12 cases (Table 1). Sulfanilamide was administered in 1, beginning forty-eight hours after onset. In this case, the quantities given were small

Watery extracts of the adrenal cortex were given in 10 cases. Desoxycorticosterone acetate alone was used in 2 patients,¹⁵ and in conjunction with watery extracts in 3 cases,^{5,12} as well as in the case reported below. The administration was unavoidably delayed for as long as thirty-six hours in 1 patient,³ despite which the authors believe that it played an important role in maintaining the equilibrium between the tissues and the circulation, was definitely responsible for the stabilization of the blood pressure, and stimulated carbohydrate metabolism. It appears to have aided materially in terminating the stupor. The dosages of cortical hormone have not been large, in 1 case only 20 cc. of the watery extract being given during the second day after the

†Two cases of recovery mentioned but not described in detail.

‡Two cases of recovery mentioned but only one described in detail.

§Patient's serum subsequently gave a positive complement-fixation test with meningococci.

until the seventh day; antimeningococcus serum was injected shortly after onset and was continued with apparently good effect.¹¹ Sulfathiazole was used in 2 cases,^{3,12} sulfapyridine in 1,¹⁴ and sulfadiazine in the remaining 8. Although the azotemia and the abnormal urinary findings appear to contraindicate the use of sulfonamides, in no case has a renal complication been described. Moreover, the ready availability of these compounds and the severity of the condition under consideration amply justify their use either separately or in conjunction with antimeningococcus or other immune serums.

Antimeningococcus serum was employed for 3 patients, who appear to have responded no more rapidly than those in whom sulfonamides were used alone.

fulminant symptoms began.¹⁶ Another patient was given 10 cc. nine and twenty hours respectively after the acute onset, followed by 10 mg. of desoxycorticosterone acetate at the thirtieth hour and daily thereafter for five days.¹⁷ One case received 50 cc. of watery extract within the first twenty-four hours and none thereafter.¹¹ This had a striking beneficial effect on the blood pressure and mental status before either sulfonamides or antimeningococcus serums were employed. Sharkey¹⁴ gave a total of 70 cc. of watery extract in four days, after which time his patient was out of danger. The largest doses of hormone were given by McCarty and Infield,¹⁵ who used desoxycorticosterone acetate exclusively, administering 10 mg. every two hours until a systolic blood pressure of over 100 was obtained. Unfortunately, neither of their cases is

described in detail. Although desoxycorticosterone acetate is not a complete substitute for cortical deficiency, its ready availability and its profound effect on the blood pressure and the distribution of electrolytes warrant its routine use in all suspected cases of the Waterhouse-Friderichsen syndrome. In careful reading of the reports of the cases of patients who recovered, one gains the impression that a major portion of the early improvement in

Epinephrine was used with little recorded effect. Camphor and Coramine served as stimulants during the cyanotic phase of collapse in most of the patients, but their real value should be questioned.

Laboratory Findings

Values for sodium and potassium were normal in 2 of the patients in whom determinations were

FIGURE 1.

mental status must be attributed to the hormonal therapy used.

The importance of cortical hormone in the treatment is still further emphasized by Haas's² description of his third case, which received adequate sulfonamide therapy but no hormone. The patient's condition grew steadily worse, with increasing stupor and death, nine hours after hospitalization and twenty hours after the onset of fulminant symptoms.

All the patients who recovered received liberal supportive treatment, chiefly in the form of intravenously administered glucose and saline solutions.

made,^{11,12} as well as in our case, but a low sodium value was noted in Bush and Bailey's⁵ patient; the chloride was extremely low (216 mg. per 100 cc.) initially in the case reported by Meyer,⁶ to rise after recovery to 472 mg. Peabody's¹⁶ patient had a normal chloride on admission. In such an acute condition, marked changes are more surprising than normal values since one would hardly expect to find variation in the electrolytes until there had been some depletion of readily available stores in interstitial fluid chambers. Even in patients with Addison's disease, Wilder and his associates²¹ have demonstrated that the serum levels for these sub-

stances may be normal despite profound alterations in their behavior.

Histologic changes in the liver have been described in 2 cases of purpura fulminans in which the patients lived for eighty and eighty-eight hours, respectively.²⁰ In both patients, death was ascribed to hepatorenal failure. The case reported here is apparently the only one in which an attempt was made to appraise liver function during life.

CASE REPORT

A 63-year-old woman was admitted to the hospital in a deep stupor within 1 hour after she had collapsed at work. She had had a sore throat 3 days prior to hospitalization and a mild headache the evening before. It was subsequently revealed that she had had mild exertional dyspnea and hypertension for 5 years and an equivocal history for 20 years of pernicious anemia, which had been controlled by occasional

urinary abnormality. A blood Wassermann test was negative, but a Kahn reaction was +. The white count was 30,200, with 90 per cent neutrophils, of which 30 per cent were immature. The red-cell count was 3,700,000, with 78 per cent hemoglobin and a color index of 1.05. No organisms were found in direct smears of the spinal fluid. Stained smears from petechiae showed gram-negative biscuit-shaped diplococci, and cultures from the blood, spinal fluid, and petechiae yielded meningococci. The icteric index, the van den Bergh reaction and the blood phosphorus and phosphatase were all within normal limits; the cephalin flocculation reaction was + + + +.

The history of acute onset with collapse, the purpura, the hypotension (100/50) despite fundoscopic evidence of hypertension, the cyanosis and the septicemia led to the conclusion that the case was one of acute adrenal insufficiency of the Waterhouse-Friderichsen type.

The patient was given 10 cc. of watery adrenocortical extract intravenously immediately, and two intramuscular injections of 10 mg. of desoxycorticosterone acetate each, 5 hours apart. A second 10-cc. dose of cortical extract was given with 1000 cc. of 5 per cent glucose in saline solution. Within the 1st hour, the blood pressure became unobtainable; Cor-

of liver extract. One son had pernicious anemia; the family history was irrelevant.

Temperature on admission was 102°F. The skin had many petechiae, especially over the extremities and a diffuse, purpuric eruption, chiefly over the trunk and fingers were cyanotic. The pupils reacted to light in accommodation. The fundi showed minimal arteriovenous nicking. Otorhinolaryngologic examination revealed many mucosal petechiae. The neck was soft. A few fine, moist rales were heard at the base of the lungs. The heart sounds were distant and of poor quality. Aortic second sound was accentuated. There was aortic murmur with maximal intensity over Erb's point transmitted downward toward the apex. The blood pressure was 100/50 and the pulse 120, with a sinus rhythm. Tendon reflexes were hypoactive throughout. Brudzinski's sign was present, Babinski's reflex was absent.

The patient's reaction was absent. She showed an anorectic pressure equilibrium, with free fluid. She showed in the test for c., the pro-entation, 60 min. ts were. equiv. .3 milliterol

mine was given intravenously and oxygen administration was begun. Within 5 hours of the initiation of adrenal substitution therapy, the blood pressure had risen and remained near that level for the balance of the hour period. The initial dose of sulfadiazine was given intravenously by infusion at the rate of 7.5 gm. in 5 hours, continued intravenously at the rate of 1 gm. in 4 hours until the patient became conscious.

During the 1st night, the patient was extremely confused and sufficiently irrational to require restraint. The next morning (approximately 12 hours after admission) she was lucid and able to take medication orally. Thereafter she was given sulfadiazine by mouth at the rate of 1 gm. every 4 hours with large doses of bicarbonate of soda. Vitamins B₁ and C were given parenterally in large doses to reduce the purpuric diathesis and to diminish the chances for acutal vitamin C deprivation through adrenal damage. The patient was started on digitalis therapy, not because there was evidence of cardiac decompensation but rather as a precautionary measure in a toxic patient past the age of 60.

After the first day, 5 cc. of cortical extract was given twice daily for 1 week. Vitamins K and C were continued throughout the hospital stay. The sulfadiazine, for which a blood level of 9 mg. per 100 cc. had been established, was continued daily for 10 days at the rate of 1 gm. every 4 hours. The temperature (Fig. 1) dropped to normal in 24 hours, but rose the following day to 101.2°F., from which level it fell to normal in 14 days. (It is interesting to note that the temperature followed the discontinuation of the therapy and that, although the cyanosis and

administration of corticosteroids to 140/90 in 24 hours and was

patient was respectively

of desoxy-

The

purpura subsided relatively rapidly, small furuncles appeared over the lower extremities in petechial areas despite the sulfonamide treatment.)

The blood pressure throughout the 1st week was maintained around 160/90 and during the 2nd week around 140/60, with one drop to 115/45, which occurred 3 days after the cessation of adrenal substitution therapy. For 3 more days, it fluctuated between 115/45 and 135/70, but then resumed its previous amplitude at around 160/90.

Throughout the course of the disease, the urine was negative except for traces of albumin. Within 2 weeks, the sedimentation rate of the red cells was 5 and 30 mm. in 15 and 50 minutes, respectively. Wassermann tests were repeatedly negative, but the Kahn reaction was successively + + + +, + +, + + + +, + + + +, + + + + and + + +. There was a gradual diminution in the white-cell count to 7000, with normal distribution of the various types of cells. The red-cell counts were repeatedly between 3,600,000 and 3,900,000, and the hemoglobin between 78 and 83 per cent. Four days after admission, the nonprotein nitrogen had dropped from 2.5 to 32.0 mg. per 100 cc., and remained normal thereafter. The blood creatinine and blood sugar were not pathologically altered on any of a number of serial examinations. The

The finding of relatively normal serum sodium, potassium and chloride levels is not astonishing in view of the work of Loeb, Atchley, Benedict and Leland,²³ who observed that even when total adrenalectomy was performed in animals the daily rate of the reduction in sodium was as little as 2.3 milliequiv. per liter. Other workers have noted that alterations in electrolyte levels may be relatively small, even in cases in which there is definite Addison's disease.²¹ This patient showed the marked elevations in non-protein nitrogen and creatinine that are generally manifest in Addison's disease during crisis. Since dehydration was not present, this finding emphasizes the close functional connection between the kidney and the adrenal cortex.

The + + + + cephalin flocculation test indicated an active process in the parenchyma of the liver.

ing blood sugar and the levels obtained at half-hourly intervals after the ingestion of 100 gm. of glucose were respectively 105, 180, 185, 190 and 145 mg. The basal metabolic rates on two occasions were -7 and -4 per cent. The spinal fluid showed a gradually complete recession in the inflammatory process. The icteric index rose to 11 the second week, and the van den Bergh reaction was simultaneously delayed; hereafter, the former was normal and the latter negative. The cephalin flocculation response decreased from + + + + to negative in 4 weeks. The total blood cholesterol increased from an initial value of 122 mg. per 100 cc. with 45 per cent esters to 210 mg. with 75 per cent esters. The serum protein, chloride, potassium and sodium were within normal limits in each of four determinations (Table 2).

DISCUSSION

Hyperglycemia was an unexpected finding in this case. It had been previously observed, however, in an acute hemorrhagic adrenalitis that was proved post mortem.²² The normal values subsequently obtained and the normal glucose tolerance noted after recovery from the acute episode in this case suggest that a trigger mechanism released adrenalinlike substances during the collapse of the organism, which secondarily elevated the blood sugar.

This was confirmed by the low total cholesterol, a diminution in the percentage of esters and an elevation of the icteric index. Later all these values returned to normal, suggesting the transient nature of the disturbance and the close relation between hepatic, renal and adrenal activity. It is, of course, possible that the icteric index rose as a result of ecchymotic and petechial hemorrhages.

The acute onset of the disease, associated with collapse, the rapid development of the cyanosis, the petechiae and the purpura, and the hypotension, the hypotonia and the hyporeflexia all indicated an acute adrenal insufficiency of the Waterhouse-Friderichsen type. The early and vigorous institution of therapy was responsible for sustaining the patient during the stage of onslaught with depressed or absent adrenocortical activity. Whether adrenal hemorrhage, simple edema or edema with petechial hemorrhages occurred, it is impossible to say. In any event, without therapy the prognosis would have been hopeless.

In view of the present high frequency of meningitis and the surprisingly high percentage of cases developing the Waterhouse-Friderichsen syndrome, it is important that the disease be borne in mind whenever a sudden state of collapse with purpura occurs in meningitis or following a simple sore throat. That 12 cases have recovered under appropriate therapy emphasizes the necessity for early diagnosis and treatment.

SUGGESTED THERAPEUTIC ROUTINE

The pathogenesis of the Waterhouse-Friderichsen syndrome and the rather uniform clinical course of the untreated cases afford an unusual opportunity to standardize the therapeutic regime. Certain conditions may be specifically met:

The pulselessness, cyanosis and state of collapse may warrant the use of Coramine, epinephrine or caffeine sodium benzoate, the values of which are probably in the order named. Dosages should be large and should be repeated on indication, although this is usually unnecessary. Such therapy is in no way fundamental, and there are those who doubt its usefulness, but it is believed that in the case reported such emergency treatment was of supportive value while other therapy was being arranged.

The first treatment for the insufficiency of the adrenal cortex should be 20 cc. of water extract, administered intravenously in 500 cc. of 2 per cent sodium chloride solution containing 5 per cent glucose. At least two and a half hours should be allowed for this infusion. As soon as it is well started, 15 mg. of desoxycorticosterone acetate should be given subcutaneously or intramuscularly; 10 mg. should be injected thereafter every eight hours until the systolic blood pressure is persistently above 100. After that, 10 mg. may be given daily until convalescence is well established, with normal temperature, pulse and blood pressure.

The associated infectious process should have vigorous treatment from the start. If the pneumococcus is the offending organism, it is well to begin treatment with penicillin, if available. An initial dose of 15,000 to 20,000 units intrathecally should be followed by 20,000 to 40,000 units intramuscularly every three hours. In the severer cases, the intravenous route may be employed, preferably by the continuous-drip method. It still seems wise, however, to avoid this route whenever possible, since there is some likelihood of producing a further febrile reaction or a thrombophlebitis. If the usually found meningococcus or any other bacterium except the pneumococcus is present, sulfonamide therapy should be vigorously followed. Sulfadiazine seems to be the agent of choice, since it probably penetrates the spinal canal more readily than do any of the others.

An initial dose of 3 gm. of the sodium salt should be given intravenously as a 5 per cent or weaker solution. In any event, not less than half an hour should be required for its administration. Subsequently, 2 gm. should be used every four hours until oral administration is possible, when the dose should be reduced to 1 gm. every four hours. Sulfonamide treatment is not contraindicated by the azotemia present in these cases. Should this treatment fail, penicillin as above described should be tried without delay.

In support of the activity of the adrenal cortex, it is possible that vitamin C has specific value. One of the crystalline preparations for intravenous use should be employed during the period of stupor. Renal loss is decreased by using several small doses instead of a single large one. The total for the day varies in individual cases from 100 to 500 mg., and can be conveniently administered along with the necessary infusions. If the bleeding tendency is great, there is at times a lowered percentage of prothrombin. Whether or not this occurs, vitamin K or a vitamin K-active substance, such as 2-methyl-1,4-naphthoquinone, may be given empirically. The latter is water soluble and may be administered intramuscularly in doses of 1 to 2 mg. daily.

SUMMARY

Recovery from the Waterhouse-Friderichsen syndrome is recorded in the case of a sixty-three-year-old woman with a past history of hypertension. Treatment included sulfadiazine and adrenocortical hormone.

Eleven previously reported recovered cases are briefly summarized, particularly in relation to the therapy received.

The improved prognostic outlook for patients with the Waterhouse-Friderichsen syndrome is stressed.

CASUALTIES IN THE SOUTH PACIFIC

COMMANDER H. E. KENNARD (MC), U.S.N.R.

TWENTY months' duty in the Southwest Pacific gave me the opportunity to see and participate in the care of many war wounded. The first fourteen months were passed in New Zealand, following which a transfer northward brought my unit close enough to the Solomon Islands campaign to receive battle casualties from there by air.

Duty in New Zealand was very pleasant. The country is roughly a thousand miles long and one to two hundred miles wide. It is made up of two large islands, with a narrow strait between. The total population is only 1,600,000. The climate is delightful. It is much like New England, except that summers are cooler and winters are warmer. At the location of the hospital, the average summer temperature was only 15° warmer than the average winter temperature. During the entire year there was only one light flurry of snow, but there were occasional frosts during the winter months of July and August. Fishing and hunting were excellent, but we were too busy to get much time for outings.

The New Zealanders were incredibly hospitable to the Americans. On several occasions, large parties of hospital patients were invited to spend a week or more on convalescent leave at various New Zealand towns. At these towns, we were most hospitably entertained as guests by the New Zealanders in their private homes. With plenty of beefsteak, butter and cream, the patients often gained several pounds during these periods.

In New Zealand, I was first assigned to several weeks of temporary duty with a hospital unit other than my own. This unit had been given for its grounds a large soccer field on the edge of a town. Starting from an empty, level green field, an excellent modern hospital was built and equipped in the short period of four and a half weeks. All the buildings and equipment had been brought from the United

States. The buildings were of prefabricated steel and were admirably suited for use in hospital construction. Under the supervision of a Navy civil engineer, the work was rushed to completion by the hospital personnel. During the last few days before completion of the buildings, work was remarkably rapid. I particularly recall supervising the laying of a floor in one of the storehouses the day the patients arrived. After we had started laying floor boards from one end of the building, trucks began to unload supplies onto the floor sections we had completed, before we were halfway down the length of the building. The equipment and supplies were plentiful and of the very best quality.

On the thirty-first day after breaking ground, casualties were received from the cruiser battle that took place off Guadalcanal in early August, 1942. As you will remember, four heavy cruisers were sunk — the *Quincy*, *Vincennes* and *Astoria* and the Australian cruiser *Canberra*.

On August 20, 1942, we received from a United States hospital ship 366 patients, almost all of whom had been wounded in the Solomon Islands engagement of August 7 to 9. Only one patient had died during the week aboard the hospital ship, and only one died at the New Zealand hospital. It was obvious that these men had had excellent care. Dressings appeared clean and neat; plaster casts had been carefully applied to the many fracture cases; even the sickest patients appeared well nourished and not suffering from dehydration. No patient seemed to need immediate surgery. There were many severely wounded patients in the group. Lieutenant George Crile, Jr., of Cleveland, Ohio, published an excellent article on this subject in the March, 1943, issue of the *United States Naval Medical Bulletin*. It was entitled "Experiences of the Surgical Service of the United States Naval Hospital, Auckland, New Zealand, with Casualties from the Initial Solomon Islands Engagement." To give some idea of the relative numbers of various types of injuries among these 366 casualties, Crile's figures are useful. There

*Read at the annual meeting of the New Hampshire Medical Society, Manchester, May 16, 1944.

were 114 flesh wounds, 104 compound fractures and 40 second-degree and third-degree burns. There were 11 surgical or traumatic amputations.

The flesh wounds had been treated with sulfanilamide or sulfathiazole powder. Many of the wounds had been débrided and had had foreign bodies removed. We noted in many cases that the flesh wounds that did best were those that had received as initial treatment mechanical cleansing, sulfonamide powder locally and no débridement.

Compound fractures were doing well in closed casts. We were impressed with the excellence of the Orr-Trueta method of treatment. As is generally known, it is much easier for the patient than former methods, for he has few, if any, painful dressings. There is a large saving of gauze and dressing material. This was particularly important when the supply line included several thousand miles of Pacific Ocean. With a large number of seriously wounded patients, there was a tremendous saving of valuable time for the medical officers, who would otherwise have spent long hours on tedious, painful dressings.

After several weeks with the hospital group at Auckland, I went back to the hospital to which I had originally been assigned. During the next thirteen months in New Zealand, we treated many more war casualties. I was particularly interested in burns and was given the assignment of taking care of all burn cases.

The "canned" human plasma with which naval medical units are provided was extremely valuable for treating burns in the early stages. In a base hospital, most of the burns were, of course, not fresh ones, but many patients had been given plasma during the first few hours after injury, and had benefited enormously from it. The few cases of fresh burns that were admitted to our hospital were given large amounts of plasma immediately.

A guest at the hospital, Major J. J. Brownlee, chief plastic surgeon of the New Zealand Army, described to us in detail the methods used in caring for burn cases in England during the German blitz of 1939. At that time, he had been associated with a famous English surgeon, Sir Harold Gillies. Briefly, the English method used in the New Zealand Army was as follows. The burned areas were not débrided. Blebs were not broken. Sulfonamide powder and vaseline gauze dressings were applied immediately after injury. After several days, the patient was put into a full-sized bathtub filled with warm, sterile, slightly hypertonic saline solution. After a few minutes of soaking with the dressings undisturbed, the latter were gently floated off under water. The water in the tub was changed several times until clean. After the bath the patient was lifted out onto a sterile sheet and dried with sterile towels, and vaseline gauze dressings were reapplied. Subsequent dressings were done in exactly the same manner. Masks, gowns and gloves were worn during

these procedures to prevent contaminating the open burned areas.

Immediately after Major Brownlee's talk, a bathtub was installed at the end of a ward on which the burn cases were segregated. An ordinary metal bathtub was raised two feet from the floor, so that its rim was exactly the same height as the top of a wheeled stretcher. This elevation was a distinct advantage in getting the patient in and out of the tub. It also made it much easier to work on him while he was lying there. A seventy-gallon tank was constructed on a five-foot platform beside the tub, with a thermometer on it. By hot-water and cold-water connections, the tank was filled with water at 105°F., and enough table salt was added to make a 1 per cent solution. The tub was carefully scrubbed with soap and water, wiped with Lysol solution and rinsed with saline solution before being filled with the warm salt water.

The saline solution was slightly hypertonic, on the theory that, with a greater osmotic pressure than that of the tissue fluids, exchange would be from the burned areas into the bath. The solution was so nearly isotonic and so near body temperature, however, that there was little discomfort for the patient. In fact, patients were usually reluctant to get out of the bath. With the tub nearly full, they floated comfortably, with only a slight amount of weight resting on the bottom of the tub.

A few patients were received who had been treated with tannic-acid jelly days or weeks previous to admission. The saline bath was extremely useful in soaking off the infected eschars. A patient who had been treated with tannic acid for burns incurred when a destroyer was torpedoed was particularly grateful for the bath. He had extensive burns on the face, ears, trunk, arms and legs. We came to the definite conclusion that, in the light of the present knowledge of the treatment of burns, tannic acid in any form is an inferior method of treatment.

Many cases of severe burns were treated with sulfanilamide wax spray. We used approximately the formula originated by Pendleton at the United States Naval Hospital at Mare Island, California. It is as follows:

Paraffin	1000 gm.
Liquid petrolatum	250 cc.
White petrolatum	150 gm.
Cottonseed oil	50 gm.
Sulfanilamide	50 gm.
Menthol	1 gm.
Camphor	1 gm.
Oil of eucalyptol	1 cc.

Patients treated by this method were put to bed in a warm room lying on a sterile sheet with the head on a sterile pillowcase. They were covered only by a cradle. A hospital corpsman sprayed the burned areas with warm sulfanilamide wax solution every two hours, using a common Flit gun. The red-cell count of severely burned patients was followed care-

fully, and after the first few days, whole-blood transfusions were given whenever indicated.

Before leaving the South Pacific, we had the opportunity of treating a case of severe burns with gentle-pressure dressings over vaseline gauze, together with a course of penicillin. This method seems to hold great promise of becoming the best way to treat fresh, severe burns.

Third-degree burns were cleaned up as quickly as possible and skin was grafted, using the Padgett dermatome or the Humby knife. Pinpoint grafts were used in cases in which there had been much infection. The Humby knife is an English instrument. It is much like our Blair-Brown knife, and is an extremely useful instrument.

All major skin grafts of the extremities were put in plaster casts for seven to eight days after operation. The patient was given 4 gm. of sulfadiazine a day, starting two days preoperatively and continuing until the first dressing was done, a week after operation. This first dressing was always done in the saline bath, after the cast had been removed.

Amputations were, fortunately, relatively few. I recall only one patient who had lost more than one extremity — a man who had lost both feet and one hand. Amputations were mostly surgical, and of the open or guillotine type. They had been done at some point near the front line to prevent infection or for nearly complete severance of the affected limb.

All guillotine amputations were placed in skin traction, using adhesive plaster and a pulley and weight over the foot of the bed. This was, of course, effective in the prevention of retraction of the skin edges. It also provided a much better final weight-bearing stump by lessening the amount of scar tissue and increasing the amount of normal tissue over the end of the stump.

It is extraordinary how little pain a traumatic amputation may cause. An Australian sailor from the cruiser *Canberra* gave me the following amazing story. During the battle in which his ship was finally sunk, there was a tremendous impact as a Japanese projectile struck his ship. He was spun around against a bulkhead but was able to remain in a standing position. He then observed a severed arm lying on the deck near his feet, and said that his first impulse was to feel sorry for its owner. He said that he did not realize that the arm was his own until he recognized a familiar ring on the finger.

Among several cases of penetrating wounds of the chest, I treated only one that resulted in empyema. In most cases there were varying degrees of hemothorax. Aspiration was done only for respiratory embarrassment or for diagnosis in cases of suspected sepsis.

One officer had been shot through the chest by a small-caliber bullet, which had not struck a rib. Three weeks later, when I saw him for the first time, the wounds of entrance and exit had completely healed and he appeared to be symptom-free.

Penetrating wounds of the abdomen were few. One case well demonstrated, however, the importance of meticulous examination after injury by multiple shell fragments. A large fragment had badly fractured the patient's lower jaw, diverting attention to his head. About two weeks after injury, he complained of lower-abdominal pain and inability to void. Careful physical examination showed a recently healed 6-mm. scar in the left side of the abdomen and a deep pelvic abscess. X-ray examination revealed a small particle of steel within the pelvis, which had evidently caused a small, leaking puncture of the sigmoid. The abscess was drained by rectum and the patient recovered.

The subject of foreign bodies is interesting, and we all had considerable experience with them. In one case we counted over 200 of them, mostly tiny, in the back, arms, buttocks and legs. The patient had been standing near an exploding shell on the deck of a cruiser. We came to the conclusion that foreign bodies, unless they cause symptoms or are very large, need not be removed. If they cause infection, lie in joints or cause symptoms by involving vital structures they should be removed.

After fourteen months in New Zealand, I was ordered to a base hospital on an island situated within a few hours by air of the fighting zone in the Solomon Islands. The climate there was entirely different from that of New Zealand. The weather was intensely hot and humid, with a tremendous rainfall. The hospital was well located, however, in a shady coconut grove, on top of a slope where we got whatever breeze was blowing. The natives were of the extremely black type known as Melanesians. There were also many Tonkinese laborers imported during peacetime from French Indo-China to work on the coconut plantations. Tropical diseases were well controlled by careful sanitation. Nearby swamps were drained, puddles were oiled, and natives were segregated from the shore installations, as precautions against mosquito-borne diseases.

Although this island had been notorious for malaria before the war, the sanitation was so good by the time I reached there that one could sit with impunity at an open-air motion-picture show during the evening without fear of dangerous mosquito bites. All hospital buildings were of course carefully screened against insects.

An interesting public-health measure was the picking of all coconuts, from the palms on the hospital compound. This was done because several men had been injured by falling coconuts, and also to avoid having empty coconut shells lying around as breeding places for mosquitoes. Flies, which had been somewhat of a nuisance when we first arrived on the island, were controlled by covering all latrines and garbage.

During the last few weeks of my stay in the South Pacific, penicillin became available in limited quantities. We treated 23 cases, with some improvement in all but 2 cases. One case that failed to improve

was that of a marine who had been shot through the right adrenal gland at Bougainville and had developed a large retroperitoneal and retropleural abscess. He finally succumbed to chronic sepsis and a terminal hemorrhage. The second case was that of a marine who arrived, suffering from a large subphrenic abscess, as a complication of acute appendicitis. He was given penicillin for a week before operation, without improvement. He made a good recovery after 1200 cc. of pus had been drained surgically. It might be added that the abscess cavity on two occasions was washed out with penicillin solution after operation; this may have helped his recovery.

The 21 cases that showed improvement included two patients with suppurative keratitis of the eye, both due to foreign bodies. Both had developed sepsis in the anterior chamber of the eye before penicillin was started. The ophthalmologist considered that their improvement after they were given penicillin was remarkable. Another case was that of a sailor with a septic knee joint of three days' duration, due to a small penetrating stab wound. Without aspiration or drainage, the knee improved rapidly with penicillin treatment. Other cases included a severe burn, a severe furunculosis and several compound fractures due to gunshot wounds.

All the above cases were treated with 15,000 units of penicillin in 15 cc. of 5 per cent dextrose in saline solution, given intravenously every three hours. In most cases this treatment was continued for a week—a total of fifty-six doses. One patient developed a slight phlebitis at the site of the injections, in the antecubital space. The dilution of penicillin was then doubled, giving 500 units per cubic centimeter instead of 1000. The phlebitis then subsided. No other harmful results from penicillin were seen.

Several cases of sulfonamide-resistant gonorrheal urethritis were treated with 20,000 units of penicillin intramuscularly every three hours for five doses. The dilution used was 5000 units of penicillin per cubic centimeter of saline solution. The result seemed extraordinarily good in all cases, although my transfer to the United States prevented an adequate follow-up.

Besides war injuries, there were many cases of the usual peacetime surgical ailments. Appendicitis, hernia, hemorrhoids and infected pilonidal cysts were probably the most frequent ones.

Pilonidal cysts were possibly aggravated by the hot climate and by sitting on hard surfaces, such as wooden benches and jeeps. At operation, a few small cysts that were not badly infected were excised and closed with through-and-through sutures of fine stainless-steel wire. Sulfanilamide powder was applied to the raw surfaces several times during the operation. There was not a large enough series or enough follow-up to draw definite conclusions, but the majority of the wounds closed in this manner appeared to heal by first intention.

The problem of anesthesia was an interesting one in the South Pacific. Pentothal proved extraordinarily useful for almost all types of minor operation. In the heat of the tropical islands, drop-ether anesthesia was somewhat difficult, owing to the rapid evaporation of the ether, but worked perfectly well in spite of this. Spinal anesthesia was usual for laparotomies and major procedures on the lower extremities.

We saw a few cases of filariasis, a mosquito-borne disease endemic in some of the South Sea islands. There appears to be much current rumor and misinformation about the nature of this disease. After having been bitten by an infected mosquito, the patient several months later develops a temporary lymphedema of the arm, leg or scrotum. Elephantiasis may occur as a late complication, but only after repeated infections by new mosquito bites over a long period of years. According to a doctor who spoke at the hospital after three years of peacetime practice in Samoa, a patient with filariasis need not have any fear of elephantiasis unless he remains for many years in the infected area and suffers recurrent attacks. In Samoa, the recurrent attacks of slight swelling due to filariasis are called by the natives "moo-moo." One sometimes hears filariasis referred to as the "moo-moo disease."

The patients at naval hospitals are sailors and marines. As most people know, the United States Marine Corps does not have its own doctors. Navy doctors are assigned to duty with the marines at the front, and hospitalized cases are sent back to naval mobile or base hospitals. The average sailor or marine is young and healthy. These men make excellent patients, with tremendous powers of recuperation. They complain very little and are most appreciative of a doctor's care, when such care becomes necessary. It has been a real privilege to have had the opportunity of taking care of some of these men.

* * *

The above is an account of twenty months' service in the United States naval hospitals in the South Pacific. On account of censorship regulations, most dates, places, numbers and so forth have necessarily been omitted. A few definite surgical impressions that have been gained during this work are as follows:

The combination of mechanical cleansing, sulfanilamide, and immobilization is the best way to treat most flesh wounds, and in wounds so treated, débridement is usually unnecessary and harmful.

Foreign bodies, unless they cause symptoms or are very large, need not be removed.

The Orr-Trueta method of closed-plaster treatment of compound fractures was highly successful.

Burns are best treated by gentle-pressure dressings over vaseline gauze, together with sulfanilamide or penicillin.

STENOSING TENDOVAGINITIS AT THE

(DE QUERVAIN'S DISEASE)

ALEXANDER P. AITKEN, M.D.

BOSTON

STENOSING tendovaginitis at the styloid process of the radius is a relatively frequent disease, but despite this fact it is not well known. There have been but few reports of this condition in the literature since it was first described by DeQuervain in 1895, and it is not discussed in the standard textbooks. Although the disease presents a clear-cut clinical picture, which makes the diagnosis easy, it is often unrecognized by the general practitioner or the industrial surgeon.

The disease is seen chiefly in women. With the present marked increase in the employment of women in industry it is more frequently encountered than formerly. Unless properly diagnosed and treated, its victims are subjected to a prolonged and painful period of disability.

Stenosing tendovaginitis is due to a thickening of the fibrous sheath that covers the tendons and the synovial sheaths of the abductor pollicis longus and the extensor pollicis brevis as they pass through the bony groove in the radial styloid. As the tendons emerge from this tunnel they diverge sharply, the abductor inserting into the lateral aspect of the base of the first metacarpal and the extensor inserting into the dorsum of the base of the proximal phalanx of the thumb (Fig. 1). Because of the divergence of these tendons, considerable tension is exerted on the fibrous sheath on extension and abduction of the thumb. It is thought by some that this tension, exerted repeatedly over a period of time, is the cause of the thickening or stenosis of the fibrous sheath. This may be true, but there is a definite relation between this condition and that of trigger finger or thumb. One in this series of 15 patients has developed bilateral trigger thumbs, and another had been previously operated on for trigger finger. Four have also developed mild symptoms of infectious arthritis. If trauma were the only cause, one would certainly expect to see the condition more frequently in men who do more heavy laborious work. The disease, however, does not often occur in men.

At operation the fibrous sheath, which is about 1 cm. in length, is found to be markedly thickened. At times it is nearly 0.3 cm. thick and has the consistence of cartilage. When the sheath is opened the lining synovial membrane is found to be markedly injected. Free fluid is noted in some of the more acute cases. Usually, however, the synovial membrane is bound down to the tendons by dense adhesions that can be removed only by sharp dissec-

tion. These may be appearance of pannus themselves may present de. the pressure of the stenosed

FIGURE 1. Diagram Showing the Location of the Fibrous Sheath at the Radial Styloid and the Divergence of the Short Extensor and Long Abductor on Abduction or Extension of the Wrist.

quently the tendons appear swollen on each side of the point of constriction.

The onset of the disease is usually insidious, without a history of trauma. Symptoms may be present for several months but grow progressively worse. The pain finally becomes so acute as to cause disability. The symptoms may be minimal in the housewife, but become acute if she takes up work that requires the use of the thumbs. Acute cases following a single trauma are sometimes seen. In such cases a past history of mild discomfort on certain motion can usually be obtained. The acute symptoms following a direct blow in these cases are caused by acute edema of a previously thickened fibrous sheath. In other cases they are due to an acute tenosynovitis and not to true DeQuervain's disease.

The disease is seldom seen in persons under twenty-five years of age. It occurs in industry in women whose work requires the use of forceps and in cooks who use heavy pans. Three of the reported

*Instructor in orthopedic surgery, Tufts College Medical School; junior visiting surgeon, Boston City Hospital.

was that of a marine who had the right adrenal gland, whose chief complaint was developed a large abscess down a clinical thermometer. The abscess. Frequently seen in the housewife, who complains of a tendency to drop things because of pain, and particularly of pain on attempting to wring out clothes.

In the acute stage there is severe pain over the radial side of the wrist joint, especially on motion of the thumb. The pain is localized directly over the styloid of the radius, with radiation into both the thumb and forearm. Any motion of the hand or wrist may be painful, but motions of the thumb, such as active abduction, opposition or acute flexion, as in gripping, are apt to produce the maximum discomfort. The use of forceps or hammers, which require not only gripping with the thumb and fingers but also the use of radial and ulnar flexion, are particularly apt to be painful.

On examination there is sometimes distinct swelling over the radial styloid, but this is not a frequent finding. There is acute tenderness to direct pressure over the radial styloid and over both tendons just distal to the styloid. Active abduction and passive flexion of the thumb cause acute pain at the styloid. Finkelstein* describes the following test, which is said to be pathognomonic of the disease: the thumb is placed in the palm of the hand, the fingers are flexed firmly over it, and the hand is then forced into ulnar flexion; this causes acute pain if DeQuervain's disease is present (Fig. 2). If the thumb is released, flexion of the fingers with ulnar flexion of the hand is not painful. X-ray examination of the wrist is negative. Ordinarily the above findings are so clear-cut that the condition is not readily confused with any other. Fracture of the scaphoid shows tenderness in the anatomical snuffbox but not over the tendons or the radial styloid. Motions of the thumb are not painful in scaphoid fractures, as in DeQuervain's disease.

Most patients when first seen have had pain for several weeks. All sorts of casts, splints and apparatus have been used. While immobilized, most patients are fairly comfortable; but on removal of the splints and with resumption of work, the symptoms have promptly recurred. In general, conservative treatment is not particularly successful. The acute cases of tenosynovitis are relieved by rest. Rest itself, although it may allow edema of the sheath to subside, does not cause the fibrous thickening to disappear.

The treatment of choice is surgery. The operation is simple and is followed by uniformly good results. Under novocain anesthesia an incision 4 cm. in length is made over the long abductor and short extensor of the thumb. These tendons can be readily identified, since they form the lateral boundary of the anatomical snuffbox. On opening

the thin layer of subcutaneous tissue the fibrous sheath is readily found. The sheath is split with a sharp knife throughout its length and its edges are retracted, exposing the underlying tendons and synovial sheaths. If adhesions are present between the sheaths and tendons, they are excised. It has been my custom also to excise the edges of the fibrous sheath. No attempt is made to close the sheath over the tendons, the only closure required being that of the skin. A compression dressing is applied.

Motion is started on the day following operation. Ordinarily work can be resumed two weeks after

FIGURE 2. Finkelstein Test.

The thumb is placed in the palm of hand, and the fingers are flexed firmly over it. On ulnar flexion in cases of DeQuervain's disease, acute pain is experienced over the radial styloid.

operation. There has been no recurrence in this series of cases. Because of the location of the incision and the encouragement of early motion, there has been a tendency for the postoperative scar to be somewhat keloid in type, but the results of surgery have been so satisfactory as to make it the treatment of choice. By early diagnosis and treatment not only is a prolonged painful disability prevented, but many man-hours are saved.

SUMMARY

Stenosing tendovaginitis at the radial styloid process is a frequent but seldom recognized condition. It occurs chiefly in women over twenty-five years of age. It is often a source of disability in housewives, particularly those who have recently

*Finkelstein, H. Stenosing tendovaginitis at radial styloid process. *J. Bone & Joint Surg.* 12:509-540, 1930

gone to work in war plants. The true cause of the disease is not known, but trauma plays at least a part in the aggravation or precipitation of symptoms. Once the condition is recognized as a clinical entity, the diagnosis is easy. The condition responds promptly to surgery. Many lost man-hours can be avoided if the medical profession will learn to recognize this disease and to institute proper treatment.

MEDICAL PROGRESS

SYPHILIS (Concluded)

G. MARSHALL CRAWFORD, M.D.*

BOSTON

CONGENITAL SYPHILIS

A thorough study of congenital syphilis from the standpoint of fetal autopsy findings has been reported by Dippel.¹⁰² The perivascular tissues of the liver and lungs generally yielded the largest number of spirochetes. Sixteen (24 per cent) of 67 fetuses of syphilitic mothers showed spirochetes in the tissues. It is interesting that 2 of 9 fetuses of Wassermann-negative mothers yielded spirochetes. This is an excellent illustration of the fact that negative serologic findings in the mother are no assurance against congenital syphilis of the child. It bears out the wisdom of the long-held tenet that any woman who has had syphilis should be treated throughout each pregnancy. Spirochetes were not found in fetal tissues prior to the eighteenth week of gestation. It is obvious from this that the syphilitic mother must receive therapy prior to the eighteenth week if her child is to be protected against syphilitic infection. A study of 100 syphilitic mothers and their offspring from a different standpoint has been carried out by Miller.⁶⁷ These cases are analyzed from various statistical angles, and criteria for the diagnosis of syphilis of the newborn are described. This author holds that even if all findings are negative in the child of a syphilitic mother, the infant should be re-examined every three months for the first year. It is stated that the child should be closely followed during the first five years of life and that surveillance should be continued to or beyond adolescence. One case is cited in which nothing was found until the child was nine years old. Miller does not believe that syphilis of the placenta can be diagnosed without isolation of the spirochete. X-ray examination of the long

bones has proved unsatisfactory to this author as a diagnostic measure. The last statement is contrary to the opinions of most syphilologists.

The rate for congenital syphilis in infants less than one year of age reported from Scotland for the years 1931 to 1942 inclusive showed a decrease of over 50 per cent.⁵⁸ The scheme used in Glasgow for the handling of syphilis in the mother and child is based on the general principle that venereal diseases in these patients should be treated where they are detected. Thus, the pregnant syphilitic woman receives therapy in an antenatal clinic and the congenital syphilitic child is treated in a child welfare clinic. The management of syphilis is thus considered an integral part of maternity and child welfare. Doubtless this contributes greatly toward co-operation on the part of the patient.

What seems to be a most promising report on the treatment of interstitial keratitis has been given by Stone.⁶⁹ Vitamin E in the form of wheat-germ oil was used in 10 patients with advanced interstitial keratitis, all of whom had previously received ample antisyphilitic therapy. Four patients had also received artificial-fever therapy. Vitamin E was mainly effective in hastening absorption of superficial and deep corneal exudates; it helped to relieve the associated photophobia and reduced excessive corneal vascularization and circumcorneal congestion. Its administration was carried on over a period of months. In one case, complete clearing of the cornea occurred after eighteen months of vitamin therapy, although only light perception was present in one eye, and perception of fingers in the other, when therapy was begun.

The possibility of confusion between congenital syphilis and scurvy in infants is illustrated in a publication by Levin.⁶⁰ A child of fourteen months

*Instructor in dermatology, Harvard Medical School; assistant dermatologist, Massachusetts General Hospital.

with the typical stigmas of congenital syphilis was thought to have Parrot's pseudoparalysis, although the blood reaction was negative for syphilis. Roentgenologic studies revealed periosteal hemorrhage due to scurvy, with associated rickets. This author found that the majority of infants under six months of age with congenital syphilis have low ascorbic acid levels. He believes that syphilitic infants should be given extremely larger doses of ascorbic acid at an earlier age, since some of the osseous changes ascribed to congenital syphilis are in all likelihood evidence of subscorbutic and subrachitic disturbances.

THERAPY

Penicillin

There are innumerable publications on the use of penicillin in infections of all sorts. Its usefulness has apparently been well defined, and it is most fortunately devastating in effect on *T. pallidum*. The action of penicillin on this organism has been carefully studied in vitro and in experimental animals.⁶¹ It became clear from this work that, in the treatment of human syphilis, care must be exercised to administer a sufficient quantity of penicillin to cure the patient rapidly; otherwise there is the possibility of producing a penicillin-resistant strain. In collaboration with the Penicillin Panel, the Subcommittee on Venereal Diseases of the National Research Council, the Army, the Navy and the United States Public Health Service are continuing studies to evaluate the effects of penicillin in the treatment of syphilis. The Army is operating two treatment centers where, under the supervision of specially qualified personnel, early syphilis is being treated.⁶² This therapy is being studied from several standpoints, and special procedures have been established to assure a minimum follow-up period of twelve months. The optimum dose schedule has not been determined. Some cases have received as much as 2,500,000 units in a week. The immediate response is excellent, but it should be stressed that no one can foretell the future.

The treatment of early syphilis with penicillin has been continued by Mahoney and his associates.⁶³ One million, two hundred thousand units in about eight days produced a favorable response in very early infections. An increase in probable failures in patients with secondary syphilis seemed to indicate the need of more vigorous therapy. These authors believe that an increase in the purity of penicillin would effect a distinct improvement in treatment. The development of a method for assaying the spirocheticidal activity of the product would also be of distinct value. They emphasize again that the final value of any treatment for syphilis must await the passage of time. Another group of observers headed by Moore⁶⁴ have published a preliminary report of the treatment of 1418 cases of early syphilis with penicillin. Various

treatment schedules were used, and some patients were followed as long as forty-eight weeks. Profound immediate effects were observed—the disappearance of surface organisms from open lesions, the healing of lesions and a trend toward serologic reversal. Relapse appeared to be more frequent after intravenous than after intramuscular injection of comparable doses. The lowest incidence of relapse and the most notable serologic response were in small groups of patients treated with subcurative doses of penicillin and Mapharsen. A favorable effect was also found in early asymptomatic neurosyphilis, acute syphilitic meningitis, early syphilis resistant to routine chemotherapy and infantile congenital syphilis. It was thought that the minimum dose, especially in secondary syphilis, should not be less than 1,200,000 units and that probably it should be more. Herxheimer reactions were frequent but not serious; other reactions were negligible. Smaller groups of patients with early syphilis have been reported by a number of authors with essentially the same results.

Eight clinics were selected for the study of the effect of penicillin on late syphilis, and a total of 182 cases of syphilis have been reported⁶⁵; these were preponderantly neurosyphilis (122 cases) but included benign late syphilis and late congenital syphilis. Benign gummatous syphilis of the skin and bones healed under a relatively small dosage (300,000 units). The abnormal spinal fluid in neurosyphilis was improved to some degree in 74 per cent, and definitely in 33 per cent. The symptoms in neurosyphilis improved less dramatically but to an encouraging extent. The response in interstitial keratitis was varied; at times it was strikingly favorable, but 2 of 14 patients were made distinctly worse. Therapeutic shock effects from penicillin in late syphilis may be serious and should be guarded against by reduced dosage during the first twenty-four hours. It is difficult to evaluate results in miscellaneous groups of cases of late syphilis, and much more time will be required to observe the durability of results.

Still another group of investigators have studied the use of penicillin in the prevention and treatment of congenital syphilis.⁶⁶ Although only 14 pregnant women with early syphilis and 9 infants with congenital syphilis were treated, preliminary observations indicate that sodium penicillin has a good effect in both types of case. The limited data seem to indicate that from 1,200,000 units to double that amount, in approximately eight days, is well tolerated by the pregnant woman. Reduced dosage during the first thirty-six to forty-eight hours is advocated. Preliminary results indicate that the infection is controlled and that the infants are born apparently healthy. Here again it is emphasized that the period of observation for either mother or child has not been long enough to be certain of results. The response to treatment with

penicillin was also most encouraging in the congenital syphilitic infant.

Two interesting reports have appeared that emphasize the possibility of partial suppression syphilis by the penicillin therapy of gonorrhea.^{67, 68} The amount of the drug used in treating gonorrhea is usually not over one tenth that required in the treatment of syphilis, and may be given within twenty-four hours. It is easily understandable therefore that the treatment of gonorrhea with penicillin may serve to obscure the earliest manifestations of syphilis. The progress of syphilis would not be prevented, and a latent period followed by recurrence or the appearance of late lesions might result. This suggests that, in patients with gonorrhea treated with penicillin, the period of observation for syphilis should be greatly extended.

Although most investigators observed only the Herxheimer phenomenon and a few minor reactions, some reports have appeared that may be warning notes. Hypersensitivity of the tuberculin type has been observed.⁶⁹ Urticarial reactions have been frequently observed, and one severe case of urticaria has been described.⁷⁰ The occurrence of contact dermatitis from penicillin has also been reported.⁷¹ It is to be ardently hoped that these will not be forerunners of graver systemic reactions to penicillin. One of the remarkable features of this drug has been its comparative freedom from serious deleterious side actions. One cannot help but recall the sulfonamide group, which started out almost as auspiciously but soon came to be regarded with an almost fearful respect because of the reactions accompanying the use of these drugs.

Attention should be called to the fact that penicillin is now available to a limited extent for the treatment of early syphilis in civilians. All cases must be hospitalized, both charity and private, throughout the treatment. An allotment of 1,200,000 units is available for each patient. In Massachusetts this can be obtained from the State Department of Public Health.

There is one point on which complete unanimity of opinion seems to have been achieved by all investigators in the use of penicillin. This is the fact that the results, although encouraging, must be considered preliminary. It is of utmost importance that this fact be universally realized, and it will be extremely unfortunate if the lay press overstimulates the hopes of the public. Although immediate results are comparable with the best of other intensive treatment schedules, this by no means indicates that the *T. pallidum* has been completely destroyed throughout the body. Early recurrence or late sequelae may yet occur. The most careful observations and control of penicillin-treated patients will be necessary over a period of perhaps twenty years before any conclusion can be drawn concerning the ultimate effect. Dosage has so far been purely tentative. The optimum time-dosage

relation has not been worked out. It is obvious then that the penicillin treatment of syphilis must be regarded as an experimental procedure for many years to come. New methods of administration may have to be devised. Penicillin excretion is known to be rapid, which necessitates repeated injections at intervals of three or four hours. A method of renal excretory blockade has been suggested.⁷² Thus the action of penicillin can be prolonged and a therapeutic level of penicillin maintained in the blood for a longer time. Methods of slowing and prolonging penicillin absorption from the injection site are also mentioned.

Intensive Therapy

There has been continued study of the rapid intensive administration of chemotherapy for syphilis. A preliminary analysis of results of short courses of triweekly injections of Mapharsen has been published by Eagle.⁷³ The first 4823 cases so treated are reported. About three fourths of the patients had early syphilis. Two thirds of them were given concomitant weekly injections of a bismuth compound. Triweekly injections of Mapharsen without bismuth gave uniformly poor therapeutic results regardless of dosage. On the basis of observations over a period of fifty to sixty weeks from the beginning of treatment, it is believed that triweekly injections of Mapharsen (approximately 1 mg. per kilogram), combined with weekly injections of bismuth subsalicylate (1.2 gm.) and continued for nine to twelve weeks, probably "cure" 85 to 90 per cent of the cases of early syphilis. The mortality in this series was slightly less than 0.1 per cent, but the authors believe that half these deaths were preventable. There is also a report covering the treatment of 332 cases of early syphilis with massive doses of arsphenamine by the syringe method in a period of five or six days.⁷⁴ Three to four injections were given daily. There was a distressingly high incidence of reactions, and grave complications were numerous. The percentage of satisfactory results was comparatively low, and the authors themselves concluded that the method was altogether unpractical. This is not unduly surprising, since it has been long known that arsphenamine is much better tolerated when given slowly in high dilution.

Another study has been reported by the United States Public Health Service.⁷⁵ This is an evaluation of massive arsenotherapy for syphilis as carried out in twenty-two co-operating clinics. A total of 4351 patients were treated. Several methods of administration were used, and three arsenical drugs were employed. In one series, typhoid vaccine was combined with multiple-syringe injections of Mapharsen. This group of patients gave the best results, when considered from the standpoint of "cure" balanced against reactions. It was calculated that this should prove effective in 85 to

90 per cent of cases of primary syphilis and in 70 per cent of cases of secondary syphilis. The administration of bismuth during the period of treatment appeared to improve the results. Relapses occurred in about 5 to 6 per cent of the cases of primary syphilis and in 10 to 13 per cent of those of secondary syphilis. Still another series of 487 patients with early syphilis was treated on a five-day schedule.⁷⁶ In this group the technic was intravenous-drip therapy with Mapharsen in dosages of from 900 to 1200 mg. In over half the cases bismuth was also given. The treatment fatality rate was 0.76 per cent. Fifteen per cent of all patients followed for five months or longer developed serologic or mucocutaneous relapse. Those receiving bismuth in addition to Mapharsen responded more satisfactorily. The authors estimate that the rate of "complete cure" will not be less than 70 per cent. Additional reports of smaller groups of cases show confirmatory results.^{77, 78} The intensive treatment program used by the Army has consisted of forty injections of arsenoxide, given twice weekly, with additional injections of bismuth, covering a total of twenty-six weeks.¹⁴ This system is merely a modification of a former schedule, and the total amount of drug administered (2400 mg.) is about the same. So far the shortened scheme results have been excellent and there has been no increase in toxic reactions.

Combined Fever Therapy and Chemotherapy

Thomas and Wexler⁷⁹ have continued their excellent work with the combination of arsenotherapy and fever. They have tried out several treatment schedules, seeking to avoid the grave reactions that were encountered in earlier work when a one-day treatment had been attempted. The theory back of treatment by this method considers the physiologic effects of fever in the host, which make for increased resistance to the infection, and the direct effect of heat on *T. pallidum*. Although kidney damage was alarming in some of the earlier cases, these authors⁸⁰ observed that no noteworthy renal injury was found when the fever produced by physical means was not prolonged beyond five hours. In their last report Thomas and Wexler⁸¹ review two thousand one hundred and forty-four courses of treatment administered to 2023 patients. The great bulk of these patients had primary and secondary syphilis, and the vast majority were treated with Mapharsen and typhoid vaccine. Daily injections of the former in doses of about 1 mg. per kilogram of body weight and four fever sessions induced by the latter in a ten-day period produced optimum results with a minimum of reactions of any sort. Among patients followed for six months or more after treatment, about 80 per cent showed satisfactory results; if retreatments are included the satisfactory results are 85.6 per cent.

An improvement in the use of typhoid vaccine to produce fever has been reported by Solomon and Somkin.⁸² This technic consists of the introduction of a high dilution of typhoid vaccine via intravenous drip infusion. By this means therapeutic temperature levels were reached and sustained for several hours. A simplification of this method has more recently appeared.⁸³ Lawrence⁸⁴ has applied the technic in 10 patients who were presumably immune to typhoid bacilli. Ten times the amount of typhoid vaccine originally recommended was employed with satisfactory results. Mapharsen was given at the height of the fever, and bismuth was administered twice weekly on afebrile days. It should be noted that some of the advantages of the use of typhoid vaccine to produce fever are the comfort of the patient, the freedom from a feeling of increased body heat and restlessness, which patients experience in cabinet treatments, and the avoidance of the need of supportive therapy. The mental state of the patient is also unaffected. Cohen and Hale⁸⁵ have likewise reported on the clinical application of this continuous intravenous-drip technic with typhoid vaccine. Its more effectively regulated fever is a particular advantage. It also appears to be therapeutically effective in producing fever in malaria-resistant cases. Another publication on the one-day treatment of syphilis with fever and Mapharsen is available.⁸⁶ The results were encouraging, but the series was comparatively small.

The use of malaria in the production of artificial fever in the treatment of syphilis has not been abandoned, in spite of the preponderance of reports concerning other methods of hyperpyrexia. Dattner, Thomas, and Wexler⁸⁷ treated 419 neurosyphilitic patients with malaria followed by some form of chemotherapy; of the 424 courses of treatment, 148 consisted of routine chemotherapy, and 276 of a daily injection of Mapharsen for ten days before leaving the hospital. No special differences were noted in the results of the two groups. Much time was saved in the cases in which the ten consecutive daily injections of Mapharsen injection were used. Nearly all forms of neurosyphilis were included in the series. On the basis of the spinal-fluid findings, examinations made six months or more after completion of treatment showed "satisfactory" results in 85.9 per cent. From a clinical standpoint the outcome was less satisfactory but nevertheless encouraging. An interesting survey of twenty years' work in the treatment of neurosyphilis has been published by Nicole.⁸⁸ In a series of 604 patients, 424 were treated with malaria, the intramuscular method being preferred. In 81 patients, a second attack of malaria was successfully induced, and in 15, a third attack was produced. This author believes that reinoculation attained improvements that could not have been secured by any other means. Recoveries were obtained even in acute and advanced cases, and the addition of chemotherapy led to a higher

recovery rate. A comparatively new pentavalent arsenical, Aldarsone, has been used in conjunction with artificial fever in a small series of patients.⁸⁹ The results compare favorably with those of combined artificial fever and Mapharsen therapy. Earlier use of this drug had indicated fewer ophthalmologic complications than those encountered with tryparsamide. In the present series, eye complications were observed in nearly 10 per cent of the patients, which is not encouraging.

Routine Chemotherapy

A comprehensive study of the results of routine treatment of 5326 patients with latent syphilis over a twenty-year period has been reported by Discker, Clark, and Moore.⁹⁰ Of this group there were 926 who were observed for five years or longer and who had a complete physical re-examination at the end of this observation period. Six hundred and thirty (68.0 per cent) had what was considered satisfactory results; an additional 239 (25.8 per cent) were considered probably satisfactory outcomes. The latter were those in whom there was an absence of clinical progression but in whom no re-examination of the cerebrospinal fluid was obtained. These two groups comprised 93.8 per cent of the total number observed. Although this study reports a random sample of the total group, the authors believe that their findings strongly indicate that patients with latent syphilis do extremely well irrespective of the type of treatment received. The optimum amount of therapy to reduce progression of latent syphilis to a minimum is considered to be approximately twenty injections each of an arsenical and a heavy metal.

For some years sulfarsphenamine has been held in gross disrepute by syphilologists for all purposes except the treatment of early congenital syphilis. An interesting study has been reported comparing the toxic manifestations of neoarsphenamine and sulfarsphenamine.⁹¹ A clinic of the United States Public Health Service was utilized for this work. A total of nearly seventeen thousand intravenous injections were given over a period of eighteen months; slightly more than half this number were neoarsphenamine, and the remainder sulfarsphenamine. The reaction rate for neoarsphenamine was so little less per thousand injections than that for sulfarsphenamine that it was considered of no statistical significance. Laboratory investigations indicated that sulfarsphenamine is definitely more stable than neoarsphenamine and apparently more active treponemically. This work suggests that the use of sulfarsphenamine deserves more study.

A new series of bismuth compounds has been isolated, and one in particular, dihydroxypropyl bismuthate, has been studied pharmacologically and clinically.⁹² The bismuth is not present as a free ion and does not coagulate and precipitate protein. It is stable in solutions ranging from mildly acid to

extremely alkaline in reaction. This allows it to pass through the stomach and remain soluble in the normally alkaline intestinal fluid, making intestinal absorption possible in amounts previously unattainable. Oral administration may thus produce a high and uniform blood level of bismuth, comparable to that obtained in standard intramuscular therapy. Compounds of this bismuthate series are also suitable for intramuscular injection.

TREATMENT REACTIONS

The use of crude liver extract in the prevention and relief of toxic manifestations of arsenical or heavy-metal therapy has been studied by Astrachan.⁹³ In a group of 52 patients with various systemic disturbances, previous histories of intolerance to drugs, skin eruptions and other complicating conditions, 47 were distinctly improved with the use of liver extract as a supportive measure. In all cases, arsenic or the heavy metal was tolerated when supportive liver-extract therapy was administered. In cases in which liver was used as a preventive measure, injections were given fifteen minutes before the arsenical or heavy metal was administered. Patients with gastrointestinal disturbances were the most markedly benefited.

In view of the serious renal complications that may be encountered with intensive therapy of early syphilis, it seems of value to point out that there is a type of nephrosis that may be associated with untreated early syphilis. An excellent example is reported by Klein and Porter.⁹⁴ Syphilis was not recognized as the cause of nephrosis in this case until a typical secondary eruption appeared several days after admission to the hospital. The blood serologic reactions were positive for syphilis. After the first injection of Mapharsen there was a rapid improvement in all symptoms.

Visual impairment during tryparsamide therapy has been discussed by Potter.⁹⁵ In so-called "chronic reactions," this author does not believe that the dose of the individual injection, the number of injections or the length and number of courses of injections are associated with visual effects in a consistent manner. The subjective reaction of flashes, sparks or spots before the eyes, together with visual distortion and slightly decreased central visual acuity, is said to occur in 5 to 10 per cent of patients receiving tryparsamide therapy. Objective changes are found on examination in 4 to 5 per cent of patients, with permanent unfavorable results in about 1 per cent. This type of reaction consists of contraction of the visual field and moderate depression of central vision. All these symptoms are classified as chronic, and the prognosis for the restoration of vision is good if the drug is promptly withdrawn. Acute reactions, on the other hand, usually occur prior to the fifth injection and are characterized by rapid deterioration of both central and peripheral vision. The exact nature of the reaction to

tryparsamide remains obscure. It is emphasized that close ophthalmologic observation during treatment is vital and usually provides adequate warning of impending disaster. The same author⁹⁶ has also described 4 cases of acute visual reactions among 500 patients receiving tryparsamide therapy, an incidence of slightly less than 1 per cent. The cases described are typical, and it is emphasized that the prognosis is only fair, regardless of treatment.

Anwyl-Davies⁹⁷ reports a survey of postarsenical jaundice and dermatitis occurring among a group of 3422 male patients over a period of thirteen years. About two thirds of these patients received neoarsphenamine, and the remainder Mapharsen. The neoarsphenamine-treated cases were complicated by jaundice more than twice as often on a percentage basis and developed dermatitis nearly six times as frequently as those receiving Mapharsen. This author is of the opinion that most of the post-arsenical reactions are due to decomposition products or to toxic substances occurring in the manufacture of the organic arsenicals. Additional factors, such as the use of alcohol, starvation and respiratory and renal diseases, are considered to be possible contributory influences in jaundice.

The United States Navy statistics for the year 1942 are interesting in respect to arsenical dermatitis.⁹⁸ Dermatitis comprised 49 per cent of the total reactions for that year. The incidence of arsenical dermatitis in each series of doses was 0.014 per cent. Premonitory signs occurred in 5 of the 17 cases observed.

Some of the complications of artificially induced fever in the treatment of syphilis of the central nervous system are discussed by Etter.⁹⁹ The more serious ones are hemorrhage, circulatory collapse and heat stroke. Minor complications include apprehension, restlessness, herpes simplex, nausea and vomiting. The author believes that the routine administration of dextrose by mouth and parenterally before treatment and oxygen continuously during all fever sessions prevents most complications. Additional fluid or dextrose may be required during treatment. The serious complications may require immediate termination of the fever. Winters¹⁰⁰ points out that therapeutic artificial fever may cause temporary or permanent injury to the male sexual organs. Herpetic lesions of the cornea have been reported during mechanical fever therapy¹⁰¹; 9 of 25 patients were demonstrated to have superficial punctate keratitis, some being moderately severe.

SUMMARY

From the public-health standpoint, there is room for considerable optimism in the reduced incidence of syphilis both among military personnel and among the civilian population. This is all the more remarkable in view of the fact that it has been ac-

complished during time of war. A sobering note creeps in, however, when one considers the gravity of the juvenile delinquency problem. If an increasing percentage of teen-age girls become venders of venereal disease, the foundation of civilization will indeed be undermined. Progress continues in the industrial field; in corporations in which the management proves recalcitrant, the approach may have to be through labor organizations.

False positive serologic tests for syphilis have been receiving a great deal of attention. Improvements in laboratory procedures to identify the false reactions are being attempted, and infectious diseases and other disorders giving rise to false positive reactions have been somewhat more clearly identified.

In the clinical field, certain diagnostic principles that can easily slip the mind of a busy physician not dealing continuously with syphilis are re-emphasized. Means for the identification of atypical lesions are pointed out, and the value of such procedures as lymph-node puncture is cited. Much has been written in the past year in the field of cardiovascular syphilis, and several of the more useful publications are reviewed. Excellent work has been done in the field of congenital syphilis, and one particularly promising report regarding the treatment of interstitial keratitis with vitamin E, which has seemed quite effective in promoting the absorption of corneal exudates, is cited.

Among therapeutic advances, the results obtained following the use of penicillin are outstanding. This potent drug has become available in greater quantity, and an increasing volume of study is being carried out, with most encouraging preliminary findings. Many phases of its use remain to be determined, the matter of adequate dosage not yet having been established. Other methods of rapid and intensive therapy continue to be improved, the combination of fever therapy and chemotherapy being steadily perfected. Some of the more useful and instructive reports regarding treatment reactions are reviewed.

Although penicillin therapy and some of the massive-treatment programs are perhaps the most dramatic elements of this report, it is imperative to stress emphatically the experimental nature of all this work. It must be constantly borne in mind that ten to twenty years will have to elapse before the ultimate value of any new treatment for syphilis can be accurately determined.

EDITH E. PARRIS, *Assistant Editor*

CASE 31041

PRESENTATION OF CASE

A fifty-five-year-old Greek was admitted to the hospital with severe abdominal pain and vomiting.

Three days prior to admission, after partaking freely of alcohol, the patient was awakened from sleep by severe nonradiating, midabdominal pain, at first continuous but later intermittent and cramp-like in nature. He vomited food mixed with wine-colored fluid, and on one occasion passed bright-red blood by rectum. There were no further bowel movements until entry. There were no chills or fever. A local physician was called, and hypodermic injections were administered for the pain. On the following day the pain diminished but the patient

*On leave of absence.

felt weak and remained in bed. On the day prior to admission he vomited green material on several occasions, and again immediately before entrance into the Emergency Ward. The blood pressure was said to have been 80 systolic, 50 diastolic.

The patient had had epigastric pain relieved by food and alkaline powders for two years previously. One and a half years before admission, a gastrointestinal series at another hospital had revealed a constant deformity of the duodenal bulb, which was interpreted as an ulcer. There was no apparent obstruction, the stomach being empty at the end of an hour. A Graham test at that time was negative. He had had an appendectomy eleven years previously.

Physical examination revealed a dehydrated, pale man complaining of abdominal pain. The tongue was dry and coated. The heart and lungs were negative. The abdomen was diffusely tender, but more so in the lower quadrants. There was some evidence of shifting dullness. No masses were felt, and peristalsis was diminished. A rectal examination revealed gross blood on the examining finger but was otherwise negative.

The temperature was 98.6°F., the pulse 76, and the respirations 20. The blood pressure was 120 systolic, 70 diastolic.

Examination of the blood revealed a red-cell count of 6,950,000, with 13.7 gm. of hemoglobin, and a white-cell count of 6850. The urine had a specific

gravity of 1.020, with a + test for albumin and 2 to 3 white cells per high-power field in the sediment. The serum nonprotein nitrogen was 80 mg. per 100 cc., and the protein 7 gm. The serum chloride was 93 milliequiv. and the carbon dioxide content 32.4 milliequiv. per liter. The blood amylase was 30 units per 100 cc. The prothrombin time was 29 seconds (normal, 18 to 20 sec.).

A roentgenogram of the abdomen revealed distended loops of small intestine in the upper and middle portions of the abdomen. No definite air or fecal matter was seen in the colon.

Immediately following admission a Miller-Abbott tube was passed, but the tip never reached the duodenum. Ten per cent dextrose in water and 5 per cent dextrose in saline were administered intravenously, and the patient was given several transfusions and was placed in an oxygen tent. Peristalsis remained diminished or absent. On one occasion he passed 250 cc. of dark-red blood by rectum. The temperature ranged up to 100°F. Repeated roentgenograms of the abdomen revealed some increase in the number of dilated intestinal loops. With increasing hydration, however, the patient appeared to improve clinically.

On the seventh hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: It is quite obvious that this patient presents a surgical abdomen, and it is my job to diagnose the cause of it. There are certain things in the history that I believe are of significance. The pain began in the midabdomen; at first it was nonradiating and apparently persistent, but later it became intermittent. Associated with the abdominal pain were nausea and vomiting, but it is not quite clear whether he vomited blood. It says "wine-colored fluid," and presumably there was some blood in the vomitus on the first occasion. Later he apparently did not vomit any blood. Another important fact is that he had passed bright-red blood by rectum before he came into the hospital and after he was admitted to the hospital, which to my mind means that he had some lesion of the gastrointestinal tract that was bleeding.

Of interest in his past history is the fact that one and a half years before admission a duodenal ulcer was shown by x-ray; this apparently responded well to medical treatment. At that time he also had a negative Graham test. Although I do not believe that too much emphasis should be placed on one negative Graham test, we can assume from these findings and history that the gall bladder was negative. He had had an appendectomy eleven years before admission.

The physical examination as written here is unrevealing. The only thing they tell us is that the abdomen was diffusely tender, no masses were felt, and peristalsis was diminished. Plain roentgeno-

grams of the abdomen are, I believe, of considerable help and are something that ought to be routinely done in patients with obscure abdominal lesions, especially those who come in with a history of vomiting; I should like to see the x-ray films.

DR. GEORGE W. HOLMES: These films of the gastrointestinal tract show the characteristic appearance of small-bowel dilatation. In the early films, there is no gas in the rectum or any part of the large bowel, so far as I can make out. In the later ones, there may be a little, but the striking thing about them is the definite evidence of obstruction and small-bowel dilatation.

DR. LINTON: I agree with you that these are typical films of small-bowel obstruction. The obstruction was probably in the midportion of the small bowel, perhaps at the junction of the upper and middle thirds. The Miller-Abbott tube, as you can see, was coiled in the stomach; as so often happens with the Miller-Abbott tube when you want to get it through into the duodenum, it would not pass.

There are certain conditions that one must consider as the cause of this man's symptoms. In reading over the history, the first possibility that entered my mind was a severe gastritis, since he had vomited a small amount of blood and had passed a large amount by rectum. I think that it is possible for bright-red blood that has arisen from the stomach and duodenum to be observed by rectum. Such a condition, however, would not explain this man's condition.

Was he suffering from a bleeding duodenal ulcer? It is my opinion that the history of his having had an x-ray diagnosis of duodenal ulcer is more or less of a "red herring" and plays no part in his surgical condition on entry. It is perfectly possible that he had a duodenal ulcer with a small perforation that had sealed off and that he had paralytic ileus, producing the x-ray picture that you see; but if so, there should have been more evidence of peritonitis than was observed.

Could he have had an acute pancreatitis? That diagnosis probably was considered when the patient was admitted, since they did a blood amylase test, which was within normal limits. The dilatation of the small bowel and the fact that he passed blood by rectum are against the diagnosis of pancreatitis.

Another diagnosis to consider is volvulus of the small bowel, which had produced intestinal obstruction and had resulted in melena, nausea and vomiting. That diagnosis ought to be seriously considered, but in view of the low white-cell count, the chance that he had a volvulus of the small bowel is rather slight.

One thing that I did not quite understand in the laboratory examination was the red-cell count of 6,950,000, especially since on physical examination he was noted to be pale. I wonder if that reading is correct. It could possibly be explained on the

basis of dehydration, which he obviously exhibited when he came in.

DR. BENJAMIN CASTLEMAN: Four red-cell counts are recorded; they are 8.2, 6.9, 6.0 and 5.7 million, respectively.

DR. LINTON: That is interesting.

Could he have had an intussusception? That is extremely unlikely, since intussusception occurs rarely in this age group unless it is preceded by a lesion in the bowel.

Meckel's diverticulum is another condition that produces bleeding from the rectum; but, again, I think that that is rarely seen as late in life as at the age of fifty-five years.

Of course, a malignant neoplasm of the small bowel should be considered. I cannot see that he had any definite evidence of this, except that he had passed blood by rectum, meaning that he must have had an intestinal lesion, and that he had intestinal obstruction. Primary malignant tumors of the small bowel are relatively rare, but they do occur.

Mesenteric thrombosis, either arterial or venous in origin, should be seriously considered. The possibility of its being arterial in origin and having the man survive as long as he did without surgical interference is so remote that I believe it can be ruled out on the basis of the history. Mesenteric thrombosis of venous origin does not produce gangrene of the bowel so rapidly, although it may eventually go on to gangrene as the condition continues to spread and to involve more of the blood vessels of the small intestine.

In view of the fact that we are dealing with a man who had polycythemia and hence a tendency toward vascular thrombosis, it seems to me that the likeliest diagnosis is venous thrombosis of the mesenteric veins, resulting in secondary intestinal obstruction. I fully realize that he had a prothrombin time that was above normal, but I think that thrombosis can occur with an elevated prothrombin time.

DR. EMERSON DRAKE: I might say that about two hours after admission the patient vomited several cupfuls of bright-red blood; this added to the confusion of the picture.

CLINICAL DIAGNOSIS

Intussusception?

Carcinoma of colon, with extension to small bowel, producing small-bowel obstruction?

DR. LINTON'S DIAGNOSIS

Acute small-bowel obstruction, secondary to mesenteric-vein thrombosis.

ANATOMICAL DIAGNOSIS

Double ileoileal intussusception, with added intussusception into cecum.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At operation Dr. J. Gordon Scannell found a mass in the cecum that proved to be an intussusception of the ileum into the cecum. This intussusception was easily reduced, but that was not all. The part of the ileum that had intussuscepted into the cecum was itself the seat of two intussusceptions, which the surgeon was unable to reduce. When we received the specimen in the laboratory we pulled fairly hard and found an old ileoileal intussusception, which in turn had intussuscepted into a more distal segment of ileum. It was this double intussusception that in turn had formed the intussusception into the cecum, which was reduced at operation.

When the ileum was opened there was, of course, rather severe gangrene of the bowel, and within the first intussuscepted loop was the guilty leader — a submucosal lipoma, which was completely viable. Some of you may recall a case of ileoileal intussusception that we discussed here a month or so ago in which we were unable to find any tumor that might have led the intussusception.* At that time the suggestion was made that perhaps the gangrene had caused a sloughing off of the initial tumor, which might have been a polyp. Here is a case with three intussusceptions and still the polyp that led the tumor was viable.

CASE 31042

PRESENTATION OF CASE

A five-year-old boy was admitted to the hospital with headache, listlessness and fever.

Two months prior to admission the patient had a bad cold that was said to have been "almost pneumonia." This lasted about a week, following which he appeared to recover completely. Three weeks before entry he became tired and listless. Whereas he had normally been extremely active, he lost interest in play and eating. Ten days before admission he developed a fever of 102°F., accompanied by nausea and followed in a few days by frontal headache and persistent vomiting. There were no chills, convulsions or paralysis.

The developmental history was normal, and the past history was noncontributory.

Physical examination revealed a thin, poorly developed child responding clearly to questions but lapsing into drowsy stupor when undisturbed. The skin was clear and of good color. The ears and throat were negative. The fundi were normal. Small cervical lymph nodes were palpable bilaterally. The neck was stiff and painful on flexion. The heart and lungs were negative. The abdomen was soft, and there were no masses or tenderness. The

*Case records of the Massachusetts General Hospital (Case 31021). *New Eng. J. Med.* 232:49, 1945.

Kernig sign was doubtful. The deep tendon reflexes were active and equal.

The temperature was 99.4°F., the pulse 100, and the respirations 24. The blood pressure was 100 systolic, 75 diastolic.

Examination of the blood revealed a red-cell count of 5,220,000, with 108 per cent hemoglobin. The white-cell count ranged from 10,200 to 20,650, with 74 per cent neutrophils. The urine was essentially negative. A tuberculin test was negative in a dilution of 1:1000, but positive at 1:100. Blood cultures were repeatedly negative. A Hinton test was negative.

A roentgenogram of the chest revealed a slightly hazy left lung field but no areas of consolidation. There was no enlargement of the hilar nodes.

A lumbar puncture on admission revealed clear colorless fluid under a pressure equivalent to 250 mm. of water. The total white-cell count was 95, with 70 per cent polymorphonuclears. The total protein was 105 mg. per 100 cc., the gold-sol curve 0012333100, and the Wassermann test negative.

The temperature ranged between 100 and 102°F. Repeated lumbar punctures revealed pressures up to 550 mm., a fluid becoming opalescent and a cell count rising to 350. A sugar determination was 39 mg., and the chloride 567 mg. per 100 cc. Several spinal-fluid cultures were negative, as were smears for acid-fast bacilli. A throat culture revealed a Type 22 pneumococcus.

Sulfathiazole therapy was begun on the sixth day. On the eighth hospital day a neurologic examination revealed a patient difficult to arouse and with dilated pupils, fixed to light. There was no papilledema. The gaze wandered but tended to be directed toward the right. There was a left hemiparesis, with increased tendon reflexes and an extensor plantar response on the paretic side. There was a positive Kernig sign.

Death occurred on the tenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ALLAN M. BUTLER: From the information in the summary of this case, no definite diagnosis can be made. If a diagnosis of a fatal disease for which no therapy is available is made, one must be sure that all diseases for which medical or surgical treatment might be beneficial and in which the prognosis might be favorable are ruled out.

The sequence of respiratory infection, fatigue, listlessness, moderate fever, nausea, headache and persistent vomiting over more than a few days is consistent with the dissemination of a primary tuberculous focus and the development of tuberculous meningitis, but does not exclude influenzal meningitis, brain abscess or encephalitis.

On examination the mental state of the child and the stiff neck are consistent with a diagnosis of tuberculous meningitis. A positive tuber-

culin test in a child of five, and hence one who has had no contacts at school, suggests continued exposure at home or the ingestion of unpasteurized milk. In this connection, however, it might be remarked that resistance to tuberculosis is relatively good at five years of age and hence the incidence of tuberculous meningitis is markedly less at this age than at one, two or three years. The history as given unfortunately provides no information concerning the presence or absence of continued exposure.

The description of the roentgenogram of the chest is noncommittal. Dr. Castleman has informed me that the films are not available for re-examination here but that they were interpreted as essentially negative.

The spinal-fluid findings are not specific. Before discussing them I should like to ask Dr. Castleman if the patient was given parenteral glucose and if the serum chloride was determined at approximately the time of determining the spinal-fluid chloride.

DR. BENJAMIN CASTLEMAN: Parenteral glucose was given during the period over which the spinal-fluid examinations were made. Sugar determinations on other specimens of spinal fluid were 63, 82 and 64 mg. per 100 cc. The level of serum chloride is not recorded.

DR. BUTLER: This means that the spinal-fluid sugar of 39 mg. per 100 cc. and the other relatively normal spinal-fluid sugar levels do not rule out tuberculous or other bacterial infection. Without the hyperglycemia incident to the parenteral glucose they might have been markedly diminished. The lack of information about the serum chloride concentration deprives the low spinal-fluid chloride of diagnostic significance. The elevated spinal-fluid protein would in itself tend to depress the spinal-fluid chloride. Moreover, continuous vomiting may well have produced a low serum chloride level, which would also result in a low spinal-fluid chloride. The occurrence of 70 per cent polymorphonuclear cells is rare in tuberculous meningitis but not impossible; it is more consistent with a pyogenic infection.

The failure to identify organisms on smear is consistent with encephalitis, brain abscess or tuberculous meningitis. The influenza bacillus may also be missed. The failure to culture organisms is also nonspecific. No mention is made of a film or pellicle in the spinal fluid on standing. Moreover, nothing is said about looking for tubercle bacilli in the gastric juice. If the meningitis were due to a Type 22 pneumococcus, the spinal fluid would have been purulent and the organisms would have been seen or recovered on culture.

Sulfathiazole was not administered until the sixth hospital day. This means that such therapy did not interfere with culture of the spinal fluid. It also indicates that the diagnosis of tuberculous meningitis was not clearly established.

The progress of symptoms is not diagnostic. The repeated lumbar punctures may well explain the absence of papilledema.

The possible diagnoses appear to be tuberculous meningitis, with or without miliary tuberculosis, influenza meningitis, encephalitis and, finally, brain abscess, although the absence of localizing procedures indicates that the attending physicians thought that this diagnosis was not possible.

I shall hazard the diagnosis of tuberculous meningitis, with or without miliary tuberculosis.

CLINICAL DIAGNOSIS

Meningitis (? tuberculous).

DR. BUTLER'S DIAGNOSES

Tuberculous meningitis.

Miliary tuberculosis?

ANATOMICAL DIAGNOSES

Tuberculous meningitis.

Miliary tuberculosis of lungs, liver, spleen, kidneys and bone marrow.

PATHOLOGICAL DISCUSSION

DR. CHARLES S. KUBIK: Autopsy revealed tuberculous meningitis and miliary tuberculosis of the

lungs, liver, spleen, kidneys and bone marrow. I should suppose that the listlessness, loss of interest in playing and loss of appetite noted three weeks before entry were the symptoms of more or less generalized miliary tuberculosis and that the onset of meningitis coincided with the development of headache and vomiting.

On examination of the brain the customary findings were observed. There was a subarachnoid exudate that was much more pronounced over the base of the brain and brain stem than elsewhere. Numerous tubercles of the arachnoid and pia could be seen with the naked eye and were later confirmed by microscopic examination. The lateral and third ventricles were enlarged to about four times normal size. The ependyma, particularly that of the third ventricle but also that of the lateral ventricles, was studded with tiny, barely visible tubercles that gave the ependymal surfaces a roughened appearance.

There was also a tubercle, 2 mm. in diameter, of the right cerebral peduncle, which may have accounted for the left hemiparesis. No other tubercles within the substance of the brain were found.

The bronchial lymph nodes were normal. The mesenteric lymph nodes were enlarged, but those examined microscopically showed no evidence of tuberculosis.

"MIGHTIER THAN THE SWORD"

ACCORDING to authentic information received by the Regional Office of Price Administration in Boston, hundreds of applications for extra food rations on medical grounds have been signed by physicians of this state, on the supposition that they would be turned down by the Medical Advisory Committee, actuated by more patriotic motives than can be attributed to the original signers. We trust that, although many such applications have repeatedly been filed, the actual number of physicians lending their names to such practices is not large.

One explanation given for this casual attitude toward signed statements is that they were not "sworn to." Fortunately the majority of physicians

still honor their own signatures, considering their word as good as their bond. Probably even physicians who sign false food applications would hardly consider it necessary to appear before a notary in order that a signed letter might be supposed to contain the truth, nor would they think that their checks should be certified before being honored. We are, on the whole, accepted at our own valuation until new evidence indicates the need for a reappraisal.

Rationing of the necessities of life in the critical years through which we are passing is a bitter reality that comes hard to a self-willed and indulgent people, a people who have yet to learn whether it really merits the freedom that is supposed to be the reward of victory. Special confidence has long been placed in the physician, who has held a place in our social and economic structure that would hardly be conceded to a mere vendor of nostrums or a peddler of pills. Paid or unpaid, he is, as Wendell Berge* recently indicated, a particularly esteemed public servant. The public and the nation have a right to expect that he guarantees the honesty of any document to which he affixes his name.

MEDICAL PREDICTIONS

IN two previous editorials^{1,2} the *Journal* expressed disapproval of the policy of the *Reader's Digest* in publishing articles^{3,4} that tend to misinform and mislead the public. Those opinions still stand for implications made in an article, entitled "Atabrine Fully Vindicated: Malaria, scourge of mankind, *can* be licked," appearing in the December, 1944, issue of the same periodical.

Incidentally, the current article indicates that the author has now learned that mosquito control is a major part of malaria control. Furthermore, it contains scientific evidence for his previous predictions. The major part of this evidence, however, has accumulated since 1942 through the combined labors of medical officers in the armed forces and the concentrated research of pharmacologists and malariologists. Fortunately, these medical men and scientists did not spend their time in making arm-chair predictions of things to come.

*Berge, W. Justice and future of medicine. *New Eng. J. Med.* 231: 721-729, 1944.

Although the great amount of field and laboratory experience gathered in the last two years has taught us how to use atabrine safely and more effectively, the fact still remains that this drug will not prevent infections, effect radical cures or prevent relapses in a certain percentage of men infected with tertian malaria. One cannot help but wonder what the men in the armed forces who contracted relapsing tertian malaria in the South Pacific and the medical officers who treat them have to say about the curability of malaria. Since tertian malaria produces the bulk of morbidity among people in endemic areas, the validity of the statement that "malaria can be licked" by atabrine, or by any other known drug, does not stand up to critical examination.

Endemic areas of malaria will continue to exist just so long as relapses occur to provide a seed bed of gametocytes for local anopheline mosquitoes to transmit the infection to a healthy person. Since the use of known drugs cannot prevent relapses and since modern mosquito control cannot entirely eliminate the anopheline vectors, the possibility of malaria epidemics persists. Furthermore, the elimination of malaria from the world, unfortunately, is not dependent on the cost of a dose of an antimalarial drug, of a mosquito repellent or of a lethal insecticide. The problems of malaria, venereal disease, respiratory disease and malnutrition, to mention a few of the significant menaces to public health, are firmly linked with the economic and intellectual welfare of the people.

Finally, the article under discussion criticizes the National Research Council and its committees for lack of faith in atabrine early in the war. It should be pointed out that the function of a group of medical advisers is not idly to predict that this or that drug will eradicate this or that disease. Their responsibility is to protect and save the lives of people on the basis of their judgment in obtaining and evaluating evidence for or against the use of a drug, serum or vaccine, a method of treatment or a surgical operation. Lives of people — our boys — are at stake, not merely the circulation of a magazine.

MASSACHUSETTS MEDICAL SOCIETY

EXECUTIVE COMMITTEE OF THE COUNCIL

On December 27, 1944, the Executive Committee of the Council, on the recommendation of the Committee on Membership and representatives from the supervising censors, took the following actions:

Allowed the following named fellows, applying for retirement and with all dues paid and in good standing, to retire under the provisions of Chapter I, Section 5, of the by-laws, such retirement to be effective as of January 1, 1945:

Alley, Ernest J. (Middlesex North), Billerica.
Estabrook, Charles T. (Worcester), 10 Algonquin Road, Worcester.
Painter, Charles F. (Norfolk), 520 Commonwealth Avenue, Boston.
Pease, Lewis W. (Norfolk South), 135 Webb Street, Weymouth.

Allowed the following named fellow, applying for retirement, to retire with remission of dues owed the Society under the provisions of Chapter I, Section 5, of the by-laws, such retirement to be effective as of January 1, 1945:

Miller, Samuel O. (Hampden), 73 Ellsworth Avenue, Springfield.

Reinstated the following named physicians, who had resigned from the Society while in good standing, under the provisions of the by-laws, Chapter I, Section 10:

Hatt, Ednah S. (Hampden), 720 Longmeadow Street, Longmeadow.
Woodman, Alice J. Hopkins (Plymouth), Standish Street, South Duxbury.

Reinstated the following named physicians, under the provisions of Chapter I, Section 10, of the by-laws, who had been deprived of fellowship for the nonpayment of dues, provided their arrears in dues at the time they were dropped plus the dues for 1945 be paid to the treasurer of the Society:

Canzanelli, P. (Middlesex South), 300 Mt. Auburn Street, Watertown.
Ginsberg, Max (Essex South), 70 Washington Street, Salem.
Healy, John F. (Norfolk), 374 Dudley Street, Roxbury.
LeBeau, Raoul J. (Worcester), 154 Main Street, Spencer.
Manoogian, B. J. (Essex South), 5 Holten Street, Peabody.

Remitted the dues owed the Society of the following named fellows, who are ill and incapacitated, under the provisions of Chapter I, Section 6, of the by-laws:

Keay, Harry C. (Worcester), Clinton Road, Sterling. 1942, 1943 and 1944.
Sweeney, William J. (Middlesex East), 4 Avon Street, Wakefield. 1944.

Allowed the following named fellows to change their membership from one district society to another, without change of legal residence, under the provisions of the by-laws, Chapter III, Section 3.

Butler, Allan M., Massachusetts General Hospital, Boston (Norfolk to Suffolk).
 Park, Francis E., 172 Commonwealth Avenue, Boston (Middlesex South to Middlesex East).
 Quinby, John T., 226 Marlboro Street, Boston (Norfolk to Suffolk).

The personnel of the Committee on Membership is as follows: Harlan F. Newton, *chairman*; John E. Fish, Peirce H. Leavitt, Sumner H. Remick and Samuel N. Vose. The representatives of the supervising censors are as follows: William H. Allen, H. Quimby Gallupe and Albert E. Parkhurst.

MICHAEL A. TIGHE, M.D., *Secretary*
 Executive Committee

DEATH

SISKIND — Alexander L. Siskind, M.D., of Lawrence, died May 5. He was in his seventy-eighth year.

Dr. Siskind received his degree from the College of Physicians and Surgeons, Boston, in 1890.

WAR ACTIVITIES

INDUSTRIAL HYGIENE

SICK ABSENTEEISM AND MEDICAL CERTIFICATES FOR INDUSTRIAL WORKERS

The present critical need of manpower for increased war production calls for more effort to be directed toward reduction of unnecessary absenteeism and labor turnover. Among the many factors bearing on this problem is the relation between private physicians and industrial physicians. A statement recently prepared on this subject by the Safety and Security Division, Office of the Chief of Ordnance, Army Service Forces, directed toward industrial physicians in ordnance plants, has been called to our attention because of its applicability to all plant physicians and co-operating private physicians.

This statement says, in part: "To minimize absenteeism alleged to sickness and terminations attributed to ill health, the closest possible co-operation should be maintained between plant physicians and private physicians in nearby communities. Private physicians often have no accurate information concerning health hazards associated with their patients' jobs in ordnance plants and the generally satisfactory medical and engineering measures taken for their control, and are often at a loss as to how to advise their patients regarding complaints related to work. Likewise, private physicians are not generally aware of the information concerning their patients, available from the plant physician in connection with past examinations, blood tests, x-ray findings and other diagnostic aids."

The related problem of medical certification of illness has also been brought to our attention as a matter that should be considered by the state industrial-hygiene divisions. This subject was discussed in an editorial entitled, "Medical Certificates and War Production," published in the *Journal of the American Medical Association*, issue of November 11, 1944. The private physician's responsibility is presented in this editorial as follows: "The Government and its contracting agents customarily require medical certificates to cover an absenteeism alleged to illness or a labor termination attributed to reasons of health. The medical profession is then put under pressure by thoughtless persons who see little harm in collecting disability benefits or in obtaining better jobs on pretext of illness. They fail to see the cumulative results of hundreds of thousands of such acts on critical war production. Responsibility rests squarely on the physician to act as prosecutor, defense attorney and judge before issuing such a certificate. He fails himself, his profession and the war effort if certificates are issued without due cause."

Traditionally, the doctor has been called on to champion and to be an advocate of his patient. In the main, the patient has been the one who employed him and he has instinctively defended the patient against any or all groups having impersonal interests. The doctor is called on to certify to this and to that. He must certify birth and death; the occurrence of contagious disease; the health of food handlers; and the freedom from disease of candidates for marriage. Health and accident policies depend to an appreciable extent on the knowledge and integrity of practicing physicians. Compensation statutes require medical judgments as bases to support legal judgments. One easily understands why the busy doctor labels all certification a "chore." It is true that to refuse to sign any statement his patient requests, the physician risks an irate individual, but one wonders what degree of confidence and respect the patient will have in his doctor if the latter, unwittingly or not, falls in with such a procedure to circumvent common honesty.

The tendency of some workers is to indict fumes, gases, dust and so forth for real or alleged ill health. Actually, few unskilled workers know what if any occupational hazards exist in their working environment. Such a worker, in the role of a patient, may influence the family doctor to a most astounding and untenable diagnosis. It seems opportune to urge that physicians protect themselves in this respect by using confirmatory sources of information.

State and local industrial-hygiene divisions can give the private physician information on the specific environmental health conditions in a particular plant on request, when there is any question concerning the possibility of illness being incurred on the job. They can also assist industries in developing a standard form of certificate for physicians to use in making reports and can bring this subject to the attention of medical societies as opportunity offers. Reprinted from *Industrial Hygiene News Letter* (December, 1944).

NOTICES

BOSTON GASTROENTEROLOGICAL SOCIETY

The next meeting of the Boston Gastroenterological Society will be held in the Thorndike Amphitheater of the Boston City Hospital, on Wednesday, January 31, at 12:00 m. Dr. George W. Harley will discuss "Twenty Years of Tropical Medicine in Liberia."

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, February 1, at 7:15 p.m. in the classroom of the nurses' residence. Dr. Pauline Luzackas will speak on the subject "Torticollis."

NEW YORK INSTITUTE OF CLINICAL ORAL PATHOLOGY

The New York Institute of Clinical Oral Pathology will hold its one hundredth monthly conference at the New York Academy of Medicine on Monday evening, April 30. Members of the medical and dental professions will discuss the subject "A Survey of the Antibiotic Problem," both from the theoretical and from the clinical standpoints.

Members of medical, dental, public-health and other professional groups are cordially invited. For further information all communications should be addressed to G. Roistacher, Executive Secretary, 101 East 79th Street, New York 21, New York.

THE USE OF THE TERM "PSYCHONEUROSIS"

LIEUTENANT COLONEL JACKSON M. THOMAS, M.C., A.U.S.*

MANY men and women discharged from the Army for medical reasons have been classified as neuropsychiatric cases. This fact and the trend of statistics in medical journals, newspapers and magazines pertaining to war neuroses suggest that it would be unfashionable today not to show alarm at the rate soldiers are developing nervous disorders. History discloses, however, that there is a similarity between the widespread concern over the conditions generally described as psychoneuroses and the ill-founded apprehension voiced by Beard¹ in 1881, when he declared:

All this is modern and originally American; and no age, no country and no form of civilization, not Greece, nor Rome, nor Spain, nor the Netherlands, in the days of their glory, possessed such maladies. Of all the facts of modern sociology this rise and growth of functional nervous disease is one of the most stupendous, complex and suggestive.

These words refer to conditions that Beard included under the appellations "nervous exhaustion," "neurasthenia" and "American nervousness"—terms that, like Charcot's "*grande hystérie*" and Morton Prince's "multiple personality," cause a false alarm in psychiatric circles similar to that felt by some psychiatrists with reference to psychoneurosis. That many American soldiers have been judged to be victims of this malady and that the facilities of the Veterans Administration are being organized to care for numbers of neuropsychiatric cases are a matter of record and tend to make it difficult to believe that the wolf of psychoneurosis is not at the door this time. On the other hand, if the manifold conditions under which this war is being waged are borne in mind, it seems reasonable to ask what normal reactions under these ordeals might be. Alternating between battling a cunning and skilful enemy and contending with long periods of idleness, homesickness and boredom in the cold of the Arctic, in the heat and disease of the tropics and in the dust of the desert puts every man's emotions under a strain. Add to these factors delays in the delivery of mail or, still worse, the arrival of letters and hometown newspapers in which the soldier is told that the people back home are con-

tinuing to motor to Florida in the winter and to the Berkshires in the summer, and the soldier may be granted a variety of emotional reactions in his foxhole. Some of these will be psychoneurotic and others psychotic in nature, for experience has shown that in any large organization of men a certain percentage inevitably manifest mental disorder. Others, however, will be mere responses to the situation—unlinked to unconscious factors to which one is accustomed to attribute the symptoms of functional nervous disorder.

From a psychopathologic point of view, the psychoses that I have seen in this war have not differed from those observed in a busy psychopathic hospital in peacetime, except in the subject matter of the delusions and hallucinations, which vary, as they have throughout the ages, with the contemporary topics of preoccupation. This statement holds true for that group of cases regarded as acute schizophrenias, which some psychiatrists think are peculiar to this war. These cases, characterized by short periods of confusion, transitory delusions and hallucinations and quick recovery soon after admission to a hospital, are closely similar to the clinical states of emotional turmoil to which Campbell² often called attention. They vary from the latter only in that the subject matter of their pathologic beliefs is more often concerned with factors prevalent in a man's thoughts in time of war. The way the patient deals with these factors, however, in war or peace, depends on the same mental mechanisms that the normal mind utilizes in adapting itself to any condition of stress.

The practical disposition of psychoses in the Army is clear-cut. Experience has shown that the majority of these patients should be discharged from the service. Some of the psychoses instigated by infective and exhaustive states, which clear up when the organic, debilitating processes subside, are exceptions to this general policy.

A widespread misuse of the term "psychoneurosis" in the present war has made the treatment and disposition of cases placed in this diagnostic classification more complex than that of the psychoses. Some of the difficulty is due to the fact that the psychiatrist is too often unfamiliar with the life of

*Associate in psychiatry, Harvard Medical School, and superintendent, Channing Sanitarium, Wellesley, Massachusetts (on leave of absence).

a soldier in the field. Imbued with theories of abnormal human behavior, remaining within the wards of a hospital and feeling the necessity to fit every record into the prevailing order of a psychiatric system, he runs the risk of confusing signs of boredom, homesickness, reactions against discipline and the normal apprehension that many excellent soldiers experience before going into battle with symptoms of a true psychoneurosis. The borderline between normal reactions to difficult situations and emotional states that are to be regarded as symptoms of an ominous personality disorder is sometimes a narrow one. Human nature is not a standardized affair. Normal men differ in their output of energy and in their medium of self-expression. Some are more sensitive than others in dealing with their diverse inner needs and with the complex demands of military life.

The discussion of issues involved in some of the equivocal states of mind attributed to psychoneurotic mechanisms in this war may be clarified if attention is focused on concrete case histories. To this end I shall confine myself to descriptions of cases that I have examined.

CASE 1. A 34-year-old, married private first class, the father of two children, enlisted in the Air Force on September 23, 1942. His childhood had been normal. After completing high school, he attended a business college for 2 years. Thereafter he worked efficiently for 14 years for an electrical company. During that time his health was good. Soon after he enlisted in the Air Force he was assigned to the ground crew of a bomber squadron, with which unit he went to Africa in February, 1943. Early in May of the same year he spent a week in a field hospital because of an unexplained fever. When he returned to his unit, he was assigned to security guard duty at a post in advance of the airfield, to aid in protecting it against surprise attacks by the enemy. In the latter part of that month he began to be troubled by insomnia, anxiousness, spells of crying and "the jitters." He grew melancholy, feared he would never live to see his wife and children again, and deplored the fact that he had enlisted in the service. Thoughts of his family were intensified when he was cautioned to be more on the alert than usual, as a result of a rumor that enemy paratroopers had descended in the proximity of his post. The "jitters" increased, but he continued to perform his duty until July 23. On that date he reported to his unit medical officer, who at once sent him to a hospital in Egypt, where a diagnosis of psychoneurosis, anxiety state, was made. He was given Sodium Amytal and kept asleep almost continuously for 2 days. He improved but continued to be nervous and was evacuated to a general hospital some distance from the combat area. On November 11, he reached a hospital in the United States. En route home most of his symptoms disappeared. By December 7 all his symptoms had disappeared. He slept well, did not cry once after setting foot on American soil, was free of the "jitters," and asked to be returned to duty. Questioning disclosed that he had a good understanding of the problems that had troubled him in Africa. He was returned to duty with a diagnosis of simple adult maladjustment.

It is significant that this patient's internal equilibrium was not upset before he entered the Army, nor thereafter until he found himself in the proximity of dangerous combat. Confronted by death and tortured by images of his wife and children on the one hand, and prodded by a sense of duty to his country on the other, he developed the "jitters," cried and could not sleep. Such a reaction incapacitated

him at the time, but I doubt that one would have had to peer into the depths of his unconscious to see that his conflict represented no more than a struggle between an urge for self-preservation and a sense of duty.

CASE 2. A 27-year-old, unmarried sergeant entered a general hospital in England in May, 1943, because of a respiratory infection. He had been inducted into the Army in June, 1942, and soon thereafter was assigned to an organization of engineers, with which he arrived in England in February, 1943. His record in the Army was good. Until the time he entered the hospital he had never consulted a medical officer. His respiratory condition disappeared, but in the course of the usual questions pertaining to his medical history, he stated that he sometimes vomited soon after meals. This information led to a complete gastrointestinal study, which disclosed no structural disease. The case was referred to a psychiatrist, who made a diagnosis of gastric neurosis and recommended transfer to a neuropsychiatric hospital. This recommendation was carried out. In that hospital the patient reiterated that he sometimes vomited after meals but added that he was not concerned about the matter since he had occasionally vomited small amounts of food for 2 years before he entered the Army. He was puzzled, however, over the fact that he was regarded as neurotic, and volunteered that he never would have told the medical officer in the first hospital that he vomited if he had known that by doing so he would be sent to a psychopathic hospital. He stated that before he entered the Army he drove a large van regularly over a distance of 500 miles. Along the route he stopped for meals at roadside houses. If he continued his trip immediately after eating, when he had previously driven a long distance, he sometimes found it necessary to get out of the van and vomit part of what he had eaten. Having done so, he continued his trip without further discomfort. According to his statements, this was such a recognized and frequent happening with other drivers that the company physician who examined all drivers every 6 months questioned them specifically about it.

In England, the patient was an efficient driver of a bulldozer tractor. He occasionally regurgitated small amounts of food if he worked hard soon after eating, but he was not concerned about this any more than he had been before his induction, accepting it as peculiar to the type of work he performed. There was no loss of weight. After 3 weeks' observation, during which time the patient regurgitated a small amount of food on only one occasion after breakfast, a diagnosis of no disease was made and he was granted his wish to return to duty.

This case illustrates how a simple vegetative habit, a condition that may have been instigated by the nature of a patient's work, is sometimes thought to be an expression of a psychoneurotic type of conflict of emotions. On the contrary, this patient showed no concern about his gastrointestinal tract. He adapted himself well to civilian life and to the Army. It is unlikely that he would have come to the attention of medical officers but for his respiratory infection.

CASE 3. A 29-year-old, married corporal, a mechanic, participated in the invasion of Sicily. His early development was normal. After completing the 7th grade at school he worked at various jobs, finally securing a night position with an express company, which he held at the time he entered the Army. He married at 22 a girl whom he had impregnated. Their marriage was an unhappy one, owing to the wife's not showing the proper interest in the child and having illicit sex relations with other men. The patient was inducted into the Army in May, 1941. Soon after he completed his basic training he was assigned to an Ordnance organization as a mechanic. He showed no signs of nervousness before entering the Army, nor thereafter did he come to the attention of medical officers until July 10, 1943, when he took part in

the invasion of Sicily. On that occasion, as his unit debarked from barges, German artillery and dive bombers opened up with devastating effect and continued to harass the invaders throughout the day. One of the patient's friends was wounded. Fear for his own safety increased. When a bomb fell in a bivouac area and killed many soldiers, he lost control, ran back and forth on the beach, and cried out with terror. This behavior caused him to be admitted to an emergency hospital, where he remained for only a few days. He then rejoined his unit, with which he continued to do duty until the end of July, when trembling, fear, uncontrollable crying and a lack of desire for food led medical officers to evacuate him by airplane to a station hospital in Africa on July 30. Five days later he was sent to duty at a replacement pool. He soon became emotionally disturbed again and was sent to another station hospital, whence he was evacuated to the United States with a diagnosis of psychoneurosis, anxiety state. By the time he had reached a general hospital in this country on November 21, all his symptoms had disappeared. He slept well, showed no signs of anxiety, and attributed his emotional disturbance in Sicily to an inability to withstand combat conditions. He asked to be permitted to return to duty elsewhere as a mechanic, "to regain my self-respect." On December 11, a board of medical officers diagnosed his case as one of simple adult maladjustment and recommended that he be returned to duty other than combat. This recommendation was carried out, and so far as is known he is adjusting well.

The state of mind that this soldier manifested under fire is another example of the emotional turmoil that some men undergo as the result of a conflict between a fear of death and a sense of duty. Although trembling, crying and apprehension persisted after he was removed from the combat area, such was the case only so long as there was likelihood that he would re-enter it.

CASE 4. A 20-year-old, unmarried private in the Field Artillery participated in the invasion of Italy. As in Cases 1 and 3, he had no neuropsychiatric record until the time he entered a combat zone. On September 14, 1943, he was admitted to an evacuation hospital, where a diagnosis of psychoneurosis, anxiety state, severe and manifested by extreme tremulousness, fear and panic reaction, caused by combat, was made. Two days later he was transferred to a station hospital. There he was described as a very shaky, wildly staring, immature, 20-year-old boy with only 7 months' service in the Army. In the early phase of the invasion, German 88's shelled his unit's gun emplacements and during that time the patient was in a constant state of panic; he spent all his time in a foxhole. He could not recall the events of a period of 3 days. He appeared to be "frozen with fright," and whenever he heard a plane he shook violently. The diagnosis of psychoneurosis, anxiety state, was confirmed, and the patient was evacuated to a general hospital in the United States, arriving there on November 21, by which time his symptoms had disappeared. Soon after admission he stated that he felt as well as ever and expressed a desire to return to duty. Later, however, after a furlough to his home, he insisted that he should not be returned to duty because he thought that some of the symptoms he had shown in Italy would return. His attitude indicated a letdown in morale more than it pointed to a persistence of the symptoms for which he had been removed from the combat zone. He was sent to duty in the United States with a diagnosis of simple adult maladjustment.

DISCUSSION

The cases that have been described are samples of the emotional states under discussion that are frequently classified with the psychoneuroses. That there are many genuine psychoneuroses detected in the Army for the first time overseas is beyond argument. If, however, one is to retain the generally accepted concept that a psychoneurosis is a nervous

disorder dependent on complicated mechanisms of the mind involving unconscious conflicts, it is difficult to reconcile the reactions exemplified by the case histories cited with this condition. The fear, fright and tremulousness shown in Cases 1, 3 and 4 constitute a behavior pattern that has been witnessed in armies throughout the ages. Until the advent of modern psychiatry, such conduct was attributed to a variation in men's capacity to sever themselves from their usual way of life and to conquer a fear of impending death. The will to fight, morale, training, fatigue, disheartening reverses and leadership were recognized as factors able to influence a man's emotions. These factors are acknowledged in this war, but the frequency with which the diagnosis of a psychoneurosis is made raises a suspicion that psychiatrists have encouraged a shrouding of them in an ill use of terminology. In doing so they have thrown the problem of psychoneurosis out of focus with what seems to be the facts. The prompt recovery of many patients when they are removed from a difficult situation adds weight to this assumption.

I saw patients in England, members of the Air Force, who were in combat over the Continent and others who had not been in combat, and considered them unsuitable for further duty. They were returned to the United States with a diagnosis of psychoneurosis. Before they arrived, I was ordered to report for duty at the same hospital to which they were later admitted. Re-examination of some of these patients disclosed that a remarkable improvement had taken place in them, especially in those who had not been in combat. This observation opened my eyes wider to the haste that I had been guilty of in the use of the term "psychoneurosis." In some cases I had mistaken boredom, homesickness and what the British call "morale lesions" for symptoms of a nervous disorder.

Recent use of the word "anxiety" illustrates further how muddled is the present knowledge of the psychoneuroses. There are psychiatrists who regard the familiar fear of a soldier in a dangerous situation as a measure of the emotion of an anxiety neurosis. This is tantamount to calling all frightened and bewildered soldiers psychoneurotic. There was a time when "anxiety" was considered an appropriate word for the emotion present in clinical states characterized by palpitation, dyspnea, sweating, anxiousness and apprehension. Of late, however, this word has been used so loosely that it has almost acquired buoyant and ethereal qualities. This careless use of the term does injustice to the Army, the soldier and the taxpayer. So does the term "depression" when it is applied to simple nostalgias. These latter conditions were often seen in World War I. When the cause, which was absence from home or some factor related to it, was removed, the patient promptly recovered. Salmon³ cited cases who recovered on the voyage home, some

doing this so rapidly that a suspicion of malingering arose. Similar recoveries are being seen in the present war. They should allay the fears entertained with regard to some of the erroneously classified psychoneuroses.

It may be argued that a disappearance of anxiety and insomnia under the conditions cited does not constitute a cure, and that the unconscious must be exposed to remove the real trouble. This point of view may be correct for some true psychoneuroses. The tension and anxiety of the cases discussed here, however, seem to have arisen from obviously trying situations rather than from hidden conflicts.

If the reactions under discussion are to be excluded from the psychoneurotic group, it is in order to ask what name is to be given them. The idea that an emotionally upset soldier is not a particular example of a recognized disorder is disturbing to some psychiatrists. Nor does modern warfare permit the outlet that Joshua seems to have had before the siege of Jericho, when it was directed that "the fearful and faint-hearted return unto his home lest his brethren's heart faint as well as his heart."

No one who is familiar with the fleeting fashions in psychiatric nomenclature wants to be caught adding another term to the confusion. Moreover, it is obvious from what has been said that I believe that some of these cases present problems in morale, discipline and stamina. If this is so, it follows that any term connoting a mental disorder will cloud the issue. The answer to the question seems to rest in the prophylactic orientation program now under way—the prevention of states that require a stigmatizing name.

For the patients who reach a hospital, regulations permit the use of the terms "observation—no disease found" and "simple adult maladjustment." The latter term does not always fit the picture, but for the patient returning to duty it is less of a handicap when he reaches his unit or a replacement pool than the term "psychoneurosis."

QUANTITATIVE SEROLOGIC TESTS FOR SYPHILIS*

ALBERT HEYMAN, M.D.†

ATLANTA, GEORGIA

QUANTITATIVE serologic tests for syphilis have become more widely used in recent years following the introduction of intensive methods of syphilotherapy. These tests not only are useful in methods of rapid treatment but are often of considerable value in the management of various problems encountered in the diagnosis of syphilis.^{1,2} It is the purpose of this report to discuss the indications for quantitative serologic testing and to illustrate how these tests, when used judiciously, may aid greatly in the recognition of certain manifestations occurring in syphilitic infection.

The quantitative titer of syphilitic serum may be determined by several methods. The smallest amount of antigen required for a positive reaction can be measured, the least amount of complement necessary to produce fixation can be determined or, finally, the serum can be diluted until it ceases to give a positive reaction.³ The last-named technic is the one most widely used and is the method employed in our laboratory. The serologic reaction is performed with serial dilutions of serum, the reagin titer being the highest dilution of serum giving a positive result. Thus, if a serum is positive up to 1:50 dilution but negative in a 1:60 dilution, it is

said to have a titer of 50. In our patients, the quantitative Kahn test is routinely employed with serial serum dilutions of 1:5, 1:10, 1:20, 1:30 and so on. The titer is recorded in Kahn units, obtained by multiplying the maximal dilution of the serum giving a positive reaction by four. A quantitative titer below 4 units is recorded when the serum shows partial flocculation in the undiluted state and is negative when diluted.⁴ Since the sensitivity of the test is known to vary each day,⁵ a difference of positivity of one to two dilutions is usually not significant. Thus, change from 40 to 80 Kahn units must be interpreted with caution.

PRIMARY SYPHILIS

In our clinic, quantitative serologic tests are taken routinely on all patients with early syphilis, but these have proved to be of the greatest value in the cases with negative dark-field lesions. A marked rise in titer provides a simple method of identifying many such lesions as primary syphilis.⁶ A simple positive reaction in the presence of a chancrelike lesion in which no spirochetes can be found is construed by most physicians as indicative of primary syphilis. Such a reaction is, however, compatible with the diagnosis of a latent syphilitic infection and a coexisting nonsyphilitic lesion, or it may indicate a biologic false positive reaction caused by chancroidal or lymphogranulomatous infection. The

*From the Clinic for Genitoinfectious Diseases, Grady Hospital, the Department of Medicine, Emory University School of Medicine, and the Georgia Department of Public Health.

†Instructor in medicine, Emory University School of Medicine; director, Clinic for Genitoinfectious Diseases, Grady Hospital.

following case illustrates the value of an increase in titer in the diagnosis of primary syphilis.

CASE 1. L. C. H., a 25-year-old Negro, came to the clinic with a penile ulcer of 5 weeks' duration. He denied previous lesions or syphilitic treatment, and the results of previous serologic tests were not available. Physical examination was negative except for the genital lesion, which was a shallow ulceration on the glans penis 1 cm. in diameter, with a clean base and sharp edges. It appeared to be healing spontaneously. Repeated dark-field examinations revealed no spirochetes, and the Frei and Ducrey tests were negative. The quantitative Kahn test, however, showed 120 Kahn units, and within 10 days the titer rose to 600 units. This sharp rise in reagin titer indicated that the syphilitic infection had been very recently acquired.⁶ A diagnosis of primary syphilis was therefore made, and treatment was instituted.

Although the ulcer in this case was suspected of being a chancre, this could not be proved until quantitative tests were done. When a chancre is of five weeks' duration or more, as in the above case, *Treponema pallidum* may not be found in more than 50 per cent of the cases,⁷ and quantitative serologic tests become of diagnostic importance.

A sharply rising reagin titer is usually found in very recently acquired syphilis, a stationary titer indicates a syphilitic infection of some duration, and a falling titer without treatment usually represents a false positive reaction.^{6,8} A considerable proportion of lymphogranulomatous and chancroidal infections have been shown to give false positive reactions for syphilis. Such reactions, which are usually of low titer, may persist for several weeks, and mistaken diagnoses of primary syphilis may easily be made in these cases.⁹ We ourselves have on several occasions observed this phenomenon, and have become impressed with the importance of quantitative serologic tests in the presence of genital lesions that are dark-field negative.

CONGENITAL SYPHILIS

Titered reagin determinations in children born of syphilitic mothers have now become recognized procedures in the diagnosis of congenital syphilis. Since maternal reagin is often transmitted to the child by way of the placenta, serologic tests at birth are of little value. Approximately 15 per cent of positive cord tests revert to negative,¹⁰ and about the same number of negative tests become positive when repeated later in infancy. For this reason, a child born of syphilitic parents should have quantitative tests at regular intervals to determine the disappearance of the maternal reagin or the gradual appearance of his own antibodies. In addition to this method of serial testing for the diagnosis of congenital syphilis, comparative studies of the reagin titer of mother and child may also be of diagnostic value. Almost invariably, the transmitted reagin in the child is equal to or less than that in the mother.^{11,12} Hence, a reagin titer in the infant well above that found in the mother should be evidence of syphilis in the child. The following case is illustrative.

CASE 2. W. C., a 2-month-old Negro, was seen in the Pediatric Syphilis Clinic in February, 1944, with the complaint of peeling of the skin of the hands and feet. On examination he appeared poorly nourished and fretful. There was a desquamation of the skin of the palms and soles, a pseudoparalysis of the legs and enlargement of the spleen and liver. The mother had had eighteen injections of Mapharsen during the last 2 months of pregnancy and had delivered premature twins, both of whom appeared normal at birth. Cord serologic tests were not done.

On admission the Kahn test of the patient was positive, whereas that of the other twin was negative. During the following week quantitative tests on the family revealed that the patient had 1120 Kahn units and the mother 40 Kahn units, whereas the other twin continued to be negative. Roentgenograms showed extensive destruction and pathological fractures of the metaphyses of the long bones, with slight periosteal reaction. The long bones of the other twin appeared entirely normal by x-ray.

Following three injections of hismith, the patient improved remarkably, with a gain in weight and disappearance of the desquamation and pseudoparalysis. Five months later the Kahn test was 360 units in the patient and still negative in the twin.

Because of the rarity of congenital syphilis occurring in only one of twins, the possibility of transmitted reagin from the mother to the apparently infected child had to be excluded in this case. Sufficient evidence for the diagnosis of congenital syphilis was provided by the characteristic roentgenographic findings in the long bones and the reagin titer in the child, which was many times that of the mother. As noted above, however, a quantitative titer in a child less than that of its mother does not exclude the possibility of the child's having congenital syphilis.

Comparative reagin determinations in mother and child may offer an immediate method for the diagnosis of congenital syphilis. Before this method can be depended on, however, further determinations of mother and infant reagin titers are needed to confirm the observation that the transmitted maternal reagin is always less than that of the mother herself.

RELAPSING SYPHILIS

Just as in the initial syphilitic infection, there is frequently a rise of reagin titer in early relapsing syphilis. The clinical recognition of infectious relapse is often difficult, for the recurring syphilide frequently appears as a solitary atypical skin or mucosal lesion rather than the florid eruption of the original infection. In such cases quantitative serologic testing may offer considerable aid in making the correct diagnosis. This is particularly true when patients have never had serologic reversal and have had what could ordinarily be considered adequate syphilitic treatment. The following case is illustrative.

CASE 3. M. H. H., a 19-year-old girl, was known to have had syphilis since September, 1942, when she was found to have secondary lesions. Immediately following the diagnosis, she had received treatment without interruption and had taken a total of sixty-six injections of neoarsphenamine, twenty-three of Mapharsen and six of hismith. Because the serologic tests had never returned to negative, she was referred to the clinic for consultation.

The physical examination was entirely negative, and no evidence of syphilis was found. Blood taken on May 24, 1944, showed 20 Kahn units. The spinal fluid was normal, with no cells, negative Wassermann, Kahn and mastic reactions and 23 mg. of protein per 100 cc. Since the patient had had sufficient arsenical therapy, she was considered to be seroresistant and no further treatment was advised.

One month later the patient returned with erythematous annular lesions of the legs and erosions in the mouth. Spirochetes resembling *T. pallidum* were found in the dark-field preparation of the oral mucosa. The Kahn titer was found to have risen to 120 units, where it remained, and biopsy of the skin lesion was histologically consistent with secondary syphilis. A diagnosis of early infectious relapse was made, and phenarsine hydrochloride was given. With the first injection the mucous patches healed completely and the skin lesions regressed markedly.

In this case the clinical appearance of the skin eruption closely resembled erythema multiforme. The finding of spirochetes resembling *T. pallidum* could not be considered diagnostic, since they were from the mouth and there were no satellite nodes large enough to aspirate. The diagnosis of a mucocutaneous relapse was therefore based on the rise of reagin titer and the histologic appearance of the skin biopsy.

In using quantitative tests as an aid in the diagnosis of relapsing syphilis, it must be remembered that early cutaneous relapse is frequently, but not always, associated with a rise in titer of serum reagin. Some cases of infectious relapse show even a negative serologic reaction.¹² Late gummatous lesions, isolated ocular relapse and neurorelapse may show no changes in serum titer.

One of the frequent problems encountered is that of a patient who has had considerable treatment for syphilis and has finally reversed his serologic reaction, but some time later returns without clinical symptoms but with a positive reaction. The physician usually considers this condition a relapse or reinfection and reinstitutes treatment. In most cases, particularly in late syphilis, a quantitative test reveals an extremely low titer, which remains the same on repeated testing. This small amount of reagin may have been missed because of daily variations in the sensitivity of the tests in the laboratory,⁵ thus explaining the previously negative serologic reaction. In these cases what appears to be a serologic relapse is shown by quantitative tests to be seroresistance.^{3,12}

BIOLOGIC FALSE POSITIVE REACTIONS

The recognition of biologic false positive reactions is often extremely difficult, but one of the simplest aids in their detection is the use of quantitative serologic tests. A rapidly falling titer in the absence of therapy is evidence of the presence of nonsyphilitic reagin.⁸ Even if the serologic reaction does not become completely negative; a decrease of titer or other bizarre behavior should arouse suspicion, and the other recommended procedures⁸ for the detection of false positive reactions can then be applied. The following case is of interest in this

respect, for the quantitative test was the first clue to the elimination of syphilis in the diagnosis.

CASE 4. M.H., a 14-month-old Negress, was admitted to the Pediatric Ward on April 11, 1944, with paralysis of the right eye. She had apparently been well up to 3 days before admission, when the right eye was noticed to be turned in. There were no other symptoms, and the patient otherwise seemed to be in perfect health. She was born of a syphilitic mother who had taken inadequate prenatal antisyphilitic treatment, but the patient was found to have persistently negative Kahn reactions at 5-month intervals.

Physical examination revealed a somewhat irritable but well-nourished child with a temperature of 100°F. The right eye was deviated internally, and no lateral motion beyond the midline could be obtained. The pupillary reflexes were normal, and the other cranial nerves seemed intact. The examination was otherwise negative, and no abnormalities of the chest could be detected, despite roentgenographic findings of a consolidation in the left upper lung. The blood Kahn reaction was doubtful on admission, but became positive several days later and remained so throughout the hospital stay. On April 21 it was 280 Kahn units, on April 27 it was 2 Kahn units, and on May 28 it was 40 Kahn units. The spinal fluid contained 6 white cells per cubic millimeter and 38 mg. of protein per 100 cc. There was a mastic reaction of 444311, a positive Kahn reaction and a negative Wassermann reaction. The spinal-fluid chloride level was 720 mg., and the sugar was 60 mg. per 100 cc. Repeated spinal-fluid examinations showed essentially the same findings, with positive Kahn and negative Wassermann reactions, at both the hospital and the state laboratory. The white-cell count on admission was 17,000, with 82 per cent polymorphonuclear leukocytes. It remained much the same during the first 2 weeks of hospitalization, but fell to 10,000 by the time of discharge. The heterophil antibody test was negative. On May 28, a specimen of serum gave negative Hinton, Mazzini, Kline, Kolmer and Eagle reactions but continued to show a positive standard Kahn reaction. The Kahn verification test showed a nonsyphilitic type of reaction, with more precipitation at cold than at warm temperatures and a higher titer with normal saline solution than with hypertonic salt solution.¹³

Although the tuberculin test was positive, no tubercle bacilli could be found in gastric washings or spinal fluid. The temperature varied between 99 and 100°F. during the hospital stay. The roentgenographic findings did not change, and the consolidation of the lung remained the same. The final clinical impression at the time of discharge was that the patient had a primary tuberculous infection; the etiology of the cranial nerve lesion was still undetermined. Two months later, the blood and spinal-fluid Kahn reactions were negative, but no improvement was noted in either the paralysis of the eye or the pulmonary consolidation.

This occurrence of a false positive Kahn reaction in sick children with the other serologic tests remaining negative is unusual, but has been previously described by Clifton and Heinz.¹⁴

We have been struck by the high titer occasionally found in false positive reactions in children with febrile illness, the false-positive reactions usually seen in normal adults being quite low.⁸ A single titer, therefore, no matter how high, is of no value in excluding a biologic false positive test, and repeated quantitative tests for observation of unusual titer behavior are necessary. For the same reason, a rising titer is occasionally due to an intercurrent illness rather than an actual increase of syphilitic reagin itself.¹⁵ An upward trend should be verified by repeated tests before being accepted as definitive.

PROZONE PHENOMENON

The prozone phenomenon is one of the yet unexplained reactions that occasionally occur in

serology. It appears in a few strongly positive serums that give negative reactions when whole serum is used but positive reactions when dilutions of the same serum are employed. Zoning is not infrequently noted in the Wassermann test, but is somewhat less frequent in flocculation tests.³ Such reactions have been noted recently in both the Kline and Hinton tests.^{16,17} The following case of zoning in the Kahn test was detected when the titer was measured quantitatively.

CASE 5. E. K., a 30-year-old Negress, entered the hospital on January 10, 1944, complaining of postprandial abdominal distress for the previous 3 months. Physical examination revealed no abnormalities except for evidence of weight loss and midepigastic tenderness. The Kahn reaction had been reported doubtful in December, 1943, again doubtful on January 8 and also doubtful on January 10 and 12. The patient gave no history of syphilitic infection, denied previous treatment and showed no signs of syphilis on physical examination.

Because of an unusual deformity of the greater curvature of the stomach, as revealed by fluoroscopic examination, the possibility of gastric syphilis was considered. Despite the doubtful Kahn reports, a quantitative titer was requested on January 14, and the serum was found to contain more than 640 Kahn units. After gastroscopic and further x-ray examinations, the patient was diagnosed as having latent syphilis and simple gastritis, and proper diet and antisyphilitic treatment were instituted. Six months later, the Kahn titer was 20 units and the prozone phenomenon had disappeared.

On the basis of a negative history and four doubtful Kahn reactions, a diagnosis of syphilis could not be made in this case. Quantitative testing, however, revealed a prozone effect that had obscured the presence of a large amount of reagin.

The incidence of serums that show the prozone phenomenon in flocculation tests is quite low, approximately 1 per 1000.¹⁶ For this reason quantitative testing of all doubtful or negative reactions is obviously a waste of time. In the rare case, however, when there is strong clinical evidence of syphilis, quantitative serologic testing is indicated.

DISCUSSION

As shown above, quantitative serologic tests have a distinct place in the diagnosis of primary syphilis and congenital and relapsing infections and in the detection of false positive reactions and prozone effects. In intensive methods of treatment, too, the trend of the reagin titer is important in determining the immediate results of therapy, for rapid-treatment schedules are often completed before the serologic reactions have had time to reverse themselves.

Low titers are oftenest found in late syphilis and high titers oftenest in early cases, but there is so much variation that routine quantitative reactions are of little value in differentiating early from late syphilis.¹⁸ For the usual diagnostic work, therefore, the routinely used qualitative test is all that is needed, since a positive reaction, regardless of the titer, is usually diagnostic of a syphilitic infection.

Furthermore, it must be remembered that the titer of reagin is in no way related to the degree of the patient's immunity and has no bearing on the prognosis or outcome of the case.¹⁶ Although one is tempted to attach more significance to a high titer, it cannot be overemphasized that a patient with a titer of 4 Kahn units may be just as heavily infected with syphilis as one with a titer of 1000 Kahn units. This fact must be constantly borne in mind, for the temptation of the physician to interpret too much from the height of the reagin titer is difficult to resist.

SUMMARY

Quantitative serologic tests have been found to be extremely useful in the handling of various problems encountered in syphilitic infections. Serial reagin determinations may be important in the diagnosis of primary syphilis when dark-field examinations of genital lesions are negative.

Congenital syphilis in infants may be determined by comparative reagin titers in the mother and child, as well as by repeated quantitative tests during infancy. Quantitative serologic tests may assist in the recognition of early cutaneous relapse and in the differentiation of seroresistance from serologic relapse. The tests have also been helpful in the detection of prozoning and biologic false positive reactions.

Although quantitative serologic tests are indicated only in selected cases, they are nevertheless an extremely valuable tool in the diagnosis and treatment of syphilis.

CHRONIC MONARTICULAR ARTHRITIS*

JOHN G. KUHN, M.D.†

BOSTON

CHRONIC monarticular arthritis often presents difficulty in diagnosis. With insidious onset and gradually increasing disability, the history may be confusing and the clinical and laboratory findings indefinite. Roentgenologic and pathological examination in many cases suggests only chronic inflammation, with no clue concerning the original cause. With these patients, after diagnostic aids have been exhausted, one must sometimes wait and observe the further course of the articular inflammation to determine its etiology. Until a diagnosis is made, treatment must be symptomatic and

joint is evident, and is usually a preceding injury or an acute infection. When the cause is not apparent, laboratory aids frequently give the diagnosis. Rapid recovery is the rule, and when healing is delayed, the subsequent course of the disease usually leaves no doubt concerning the diagnosis. Evidences of previous inflammation in the joints are sometimes found when there are no complaints and no evidence of disability.

The location of the disease, the duration of symptoms, the clinical impression, the course and the final diagnoses in the 14 cases of chronic mon-

TABLE 1. Summary of Data in Cases of Chronic Monarticular Arthritis.

CASE No.	AGE yr.	SEX	JOINT INVOLVED	DURATION OF SYMPTOMS	PRESUMPTIVE DIAGNOSIS	COURSE	TIME FOLLOWED yr.	FINAL DIAGNOSIS
1	6	M	Right knee	12 mo.	Rheumatoid arthritis	Increasing disability	5	Tuberculosis
2	9	F	Left hip	18 mo.	Tuberculosis	Recovery	5	Chronic sprain
3	11	M	Right knee	6 mo.	Tuberculosis	Other joints involved	4	Rheumatoid arthritis
4	14	M	Left knee	6 yr.	Tuberculosis	Increasing disability	3	Tuberculosis
5	16	F	Left knee	8 yr.	Tuberculosis	Other joints involved	4	Rheumatoid arthritis
6	18	F	Left hip	6 mo.	Acute infection	Eventual ankylosis	3	Acute infectious arthritis
7	19	F	Left ankle	18 mo.	Tuberculosis	Increasing disability	2	Tuberculosis

9	31	F	Right knee	6 mo.	Acute infection	Improvement	3	Gonococcal arthritis
10	34	F	Left knee	10 mo.	Acute infection	Ankylosis	4	Acute infectious arthritis
11	37	M	Left knee	7 mo.	Tuberculosis	Recovery	7	Rheumatoid arthritis
12	42	M	Left hip	8 mo.	Tuberculosis	Died	1	Sarcoma
13	46	F	Right elbow	15 mo.	Rheumatoid arthritis	Slow progression	2	Tuberculosis
14	61	F	Right knee	6 mo.	Osteoarthritis	Slow progression	2	Tuberculosis

should be directed to the relief of symptoms and the prevention of further disability.

Fortunately, chronic inflammation in only one joint is not frequent, and this type of disease in which a diagnosis cannot be made for a prolonged period is rarer still. I have for the last ten years been recording the cases of chronic monarticular arthritis in which a diagnosis could be made only after prolonged observation. Six months of persistent symptoms was taken arbitrarily as the minimum time for considering the condition chronic. On the wards of the Robert B. Brigham Hospital 15 such patients have been observed among 2268 patients suffering from chronic arthritis. One of these, a girl of eleven with a chronic arthritis of the left hip of eight months' duration, has recently been admitted and has been under observation for only a short time. No diagnosis has yet been made, and this case is not included in the tables or in the further discussion.

Acute monarticular arthritis is relatively frequent. In most cases the cause of the inflammation in the

articular arthritis are given in Table 1. Early impressions given in our own and many neighboring clinics were often subsequently found to be wrong. The two diseases that offered the greatest difficulty in differentiation were rheumatoid arthritis and articular tuberculosis. In the average case of rheumatoid arthritis there is a gradual onset, with progression of the inflammatory process from joint to joint, followed by gradual subsidence of the inflammation, leaving varying amounts of deformity in the involved joints. When there is great variation from this clinical course, difficulties arise in making a diagnosis. In tuberculosis there is usually a mild inflammation in one joint, slowly increasing in severity concomitant with a decline in the general health. In both diseases there is often a secondary anemia, an elevated sedimentation rate and evidence in x-ray films of swelling of the soft tissues, followed by osseous atrophy. Aspiration and study of articular fluid and even biopsy may yield inconclusive results until the disease is well advanced. There is no characteristic microscopic appearance in rheumatoid arthritis. If tubercles are found, one can be relatively certain of the presence of tuberculosis. Bacteria recovered from synovial fluid are

*From the Robert Breck Brigham Hospital.

†Chief of the Surgical and Orthopedic staffs, Robert Breck Brigham Hospital.

also conclusively pathognomonic. Failing these, if the course of the disease follows no definite pattern, one is often uncertain of the diagnosis.

In a number of these patients punch biopsies were performed to make a diagnosis or to estimate the progression of the process in the joint. This procedure was done with a No. 12-gauge tri-flanged needle with a stylet, which was removed when the desired depth in the tissues was reached. A small core of tissue was then obtained by twisting the needle and applying suction through an attached syringe. The small masses of tissue removed in this manner showed either normal tissue or chronic inflammation. The tissues were identified with

fection, 1 was a slowly growing sarcoma, 1 was diagnosed hysteria, and 1 was a chronic sprain.

The diagnostic procedures employed in attempting to arrive at a diagnosis are given in Table 2. All these patients were questioned and examined both by the house officers and by the visiting staff. There was a history of slow evolution of symptoms in half of them. In the others, there was a definite preceding injury in 4 and a sudden onset with fever suggesting an acute infection in 3. In the majority of cases examination of the joint showed only mild articular inflammation, with nothing to suggest the nature or the severity of the arthritis. The x-ray examinations were not characteristic, showing in

TABLE 2. Summary of Diagnostic Aids in Cases of Chronic Monarticular Arthritis.

CASE No.	HISTORY	PHYSICAL EXAMINATION	X-RAY EXAMINATION	BLOOD	OTHER TESTS	ASPIRATION	BIOPSY
1	Slow onset	Swollen and warm joint	Bony atrophy	Moderate leukocytosis	Tuberculin positive	Fluid negative for tuberculosis	No record
2	Patient struck by wagon	Pain and muscular spasm	Haziness of joint	Normal	All negative	No record	No record
3	Slow onset; father had tuberculosis.	Slight swelling of joint	Bony atrophy	Normal	Sedimentation rate 52 mm.	Fluid negative for tuberculosis	No record
4	Patient struck while playing	Moderate swelling of joint	Haziness of joint	Moderate leukocytosis	Tuberculin plus; sedimentation rate 65 mm.	Fluid positive for tuberculosis	No record
5	Patient fell off sled	Pain and limitation of motion	Slight bony atrophy	Mild anemia	Sedimentation rate 48 mm.	No fluid	No record
6	Followed tonsillitis	Stiff joint	Beginning ankylosis	Normal	All negative	No record	No record
7	Sprained ankle	Swollen and painful joint	Bony necrosis (sequestrums)	Normal	Tuberculin plus	No record	No record
8	Gradual onset	Slight limitation and pain on motion	Negative	Moderate leukocytosis	All negative	No record	No record
9	Sudden onset; fever.	Flexion deformity and painful tender joint	Destruction of cartilage	Slight leukocytosis	Gonococcal fixation plus; sedimentation rate 89 mm.	No fluid	No record
10	Fever	Stiff joint	Ankylosis of joint	Normal	All negative	No record	Chronic inflammation
11	Gradual onset	Flexion deformity and moderate swelling of joint	Periarticular swelling	Normal	Sedimentation rate 57 mm.	No fluid	No record
12	Slow onset	Flexion deformity and muscular spasm of joint	Bony atrophy	Mild anemia	Tuberculin plus; sedimentation rate 30 mm.	No fluid	Sarcoma
13	Gradual onset	Swelling and stiffness of joint	Bony atrophy	Mild anemia	Tuberculin plus	Fluid positive for tuberculosis	No record
14	Slow onset	Flexion deformity and swollen joint	Bony necrosis	Normal	Tuberculin plus; sedimentation rate 94 mm.	Fluid positive for tuberculosis	No record

difficulty, and rarely could an opinion be given of the nature and severity of the inflammation in the joints. These attempts were soon discontinued. They demonstrated that satisfactory biopsies could be obtained only by adequate inspection of the articular cavity.

In this series, the duration of symptoms ranged from six months to eight years. The ages varied greatly, but the majority of the patients were children or young adults. The lower extremity was involved in most cases, a distribution that is observed in most injuries and infections involving the limbs. The knee joint was affected in 8 cases, the hip in 3, and the ankle, shoulder and elbow in 1 each. Of these 14 cases, only 2 proved to be rheumatoid arthritis, 1 was probably rheumatoid arthritis, 5 eventually were found to be tuberculosis, 2 were acute infectious arthritis, 1 was a gonococcal in-

fection, 1 was a slowly growing sarcoma, 1 was diagnosed hysteria, and 1 was a chronic sprain. The blood picture was usually normal. In 8 cases, the sedimentation rate (Westergren) was moderately elevated; in 3 it was normal, and in 3 it was not done since these patients were seen before the sedimentation test came into general use. The tuberculin test was positive in 6 cases. In 5 of these, the arthritis was found to be caused by tuberculosis. A strongly positive tuberculin test, although in no sense diagnostic, suggests that the inflammation is a tuberculous infection. The Wassermann reaction was negative in all these patients. The gonococcal fixation test was carried out in 6 cases; it was negative in 5 and positive in 1. It is generally reported to be positive in at least 80 per cent of cases when gonorrheal arthritis is present. Aspirations of joints gave indefinite results in 6 cases, and in 3 it showed tuberculous in-

fection. There is no record of aspiration in the other cases. Surgical biopsy was performed only when the severity of the disability suggested that this procedure might greatly modify the treatment.

CASE REPORTS

CASE 1. A 6-year-old boy 1 year before admission fell upon his right knee which gradually became more swollen and limited in motion. It was treated in an outpatient clinic with support, a sprain being the presumptive diagnosis.

Examination at admission showed a swollen, hot knee, mildly tender on pressure. There was a 30° flexion deformity. There was a slight afternoon temperature. X-ray examination of the chest was negative. The blood showed a slight anemia, with a white-cell count of 14,600. A Wassermann test was negative and a tuberculin test positive. Aspiration of the knee showed clear fluid with a few polymorphonuclear cells. Injection of the joint fluid into a guinea pig failed to give evidence of tuberculosis. X-ray examination of the knee showed swelling of the soft tissues and slight osseous atrophy. The symptoms subsided somewhat and the patient was permitted to walk with a knee support. He was discharged to a state hospital.

Four years later he was walking without a limp, there were no complaints, and the right leg was 2.5 cm. longer than the left. The unproved diagnosis at the state hospital was healed tuberculosis.

CASE 2. A 9-year-old schoolgirl was struck by a wagon on the left leg 1½ years before admission, the injury being followed by pain and limitation of motion in the left hip. The mother had died of tuberculosis but had had no contact with the patient after she was two weeks old.

Examination showed moderate limitation of flexion and abduction of the left hip. X-ray examination showed haziness of the hip joints, the chest being negative. The blood showed nothing abnormal. Tuberculin and Wassermann tests were negative. Under bed rest the symptoms subsided entirely in 3 months.

The patient has remained well for 5 years since discharge. The probable diagnosis was chronic sprain of the left hip.

CASE 3. An 11-year-old schoolboy complained of pain and swelling of the right knee of 6 months' duration. There was no history of injury. His father had a healed tuberculous lesion of the right ankle.

Examination showed moderate swelling and fluid in the right knee. There was a 20° flexion deformity. On x-ray examination there was swelling of the soft tissues. X-ray films of the chest were negative. The blood showed nothing abnormal. Wassermann and tuberculin tests were negative. The sedimentation rate was 52 mm. Injection of aspirated joint fluid into a guinea pig failed to give evidence of tuberculosis. The patient was given bed rest and a plaster cast for the right leg. The symptoms entirely subsided in 4 months. A tonsillectomy was then performed and he was discharged home.

He remained well for 4 years, when he began to have pain and stiffness in the right hip and low in the back. He was readmitted to the hospital. X-ray examination showed advanced arthritis of the spine, and the disease progressed to ankylosis of the entire spine and both hips. A severe glomerular nephritis developed. The patient is now completely helpless in a rest home. The final diagnosis was rheumatoid arthritis.

CASE 4. A 14-year-old boy was struck in play on the right knee 5 years before admission, and was treated at intervals in a hospital clinic. The symptoms partially subsided and he continued going to school, but the knee remained swollen and limited in motion. Four months before admission the symptoms became worse.

Examination showed marked swelling and limitation of motion. The white-cell count was 13,600, with 44 per cent lymphocytes. The sedimentation rate was 65 mm. Gonococcal-fixation and Wassermann reactions were negative. A tuberculin test was positive. X-ray examination of the knee showed narrowing of the joint space and thickening of the

soft tissues. The chest showed thickening about the roots of the lungs but no definite evidence of tuberculosis. Injection of fluid aspirated from the knee produced tuberculosis in a guinea pig. The boy was transferred to a sanatorium for the treatment of tuberculosis.

The diagnosis was tuberculosis of the knee.

CASE 5. A 16-year-old schoolgirl entered the hospital complaining of pain and swelling of the left knee of 8 years' duration, coming on after a fall from a sled. There was intermittent swelling but no pain. Tuberculosis was suspected in another clinic, although x-ray examination showed only slight bony atrophy. Aspiration of the joint was negative. Symptoms subsided completely after 18 months in a convalescent home. The patient remained well for 6 years but 4 months preceding admission she began to have swelling, pain and limitation of motion in the left knee, right ankle and right wrist.

On admission there was no increased heat or tenderness in the joints or other noteworthy findings. Examination of the blood showed a slight anemia, with a white-cell count of 7800. Wassermann and tuberculin tests were negative. The sedimentation rate was 48 mm. X-ray examination showed slight bony atrophy and periarticular swelling about the involved joints. During the stay in the hospital the hands and elbows and hips also became inflamed. The patient gradually improved and was discharged after 8 months.

She has since been followed in the outpatient clinic for 5 years. The only remaining disability is slight limitation of motion in the left hip and right elbow. The diagnosis was rheumatoid arthritis.

CASE 6. An 18-year-old girl entered the hospital complaining of pain and increasing stiffness of the left hip of 6 months' duration. The onset of symptoms followed an attack of tonsillitis. She was treated in a suburban hospital, where the throat infection subsided and the symptoms in the hip decreased.

Examination on admission showed moderate atrophy of the musculature of the left hip joint but was otherwise negative. The blood showed no abnormal findings. Wassermann and tuberculin tests were negative. A vaginal smear showed no gonococci. X-ray examination showed almost complete loss of cartilage at the left hip joint, with bony atrophy; there was no definite osseous destruction. The leg was made comfortable in a plaster cast with the hip held in slight flexion and abduction. All motion at the hip was soon lost, and x-ray films showed beginning bony ankylosis.

The patient was subsequently followed for 3 years. She remained well during this period, but the left leg was ankylosed. The diagnosis was acute infectious arthritis followed by ankylosis.

CASE 7. A 19-year-old Italian candy maker was admitted complaining of pain and swelling of the left ankle coming on after a sprain of the ankle 2 years before. There was a definite limp, but pain was not severe.

Examination showed extensive swelling on both sides of the ankle, with fluctuation on the outer side. The temperature was normal. Examination of the blood showed no definite abnormality. A Wassermann test was negative, and a tuberculin test was positive. The x-ray films showed necrosis of the os calcis, with several small sequestrums. Biopsy demonstrated tuberculosis.

The patient gradually improved in a convalescent hospital. There she developed a psychosis and has since been confined in a state mental hospital. The final diagnosis was tuberculosis of the ankle.

CASE 8. A 22-year-old waitress complained of pain and stiffness of the right shoulder of 6 months' duration, which appeared after a severe throat infection. The condition had remained practically unchanged until admission.

Examination showed moderate limitation of motion and slight pain on motion of the right shoulder. The white-cell count was 15,000. The sedimentation rate was 17 mm. Wassermann and gonococcal-fixation tests were negative. X-ray examination of the shoulder showed no abnormality. A psychiatric examination revealed an unstable personality

with difficulty in adjustment and frequent changes of jobs. A 3-month pregnancy had been terminated by abortion shortly before the onset of symptoms. The symptoms quickly subsided in the hospital. A better environment and more congenial employment was provided by the Social Service Department.

The patient has been followed for 6 years and has had no further trouble in the shoulder. The final diagnosis was hysteria.

CASE 9. A 31-year-old schoolteacher had pain and swelling of the right knee of 6 months' duration. There was no history of injury. A cast was applied to the knee for the relief of pain at a suburban hospital, but was soon removed. The condition remained practically unchanged.

On examination there was a 30° flexion deformity of the knee, which was tender and showed increased heat. The white-cell count was 11,350. The sedimentation rate was 89 mm. The gonococcal-fixation test was positive. Wassermann and tuberculin tests were negative. X-ray examination showed periarticular swelling with beginning destruction of the articular surfaces. A cervical smear showed no gonococci. No fluid was obtained on aspiration. Under rest and physiotherapy the symptoms slowly subsided.

After 4 months there was improved motion in the knee, which has remained unchanged for 8 years. The final diagnosis was probably healed gonococcal arthritis.

CASE 10. A 34-year-old housemaid had pain and tenderness, followed by inability to move the left knee, of 10 months' duration. She had had a fever for the first 2 weeks of her illness.

Examination showed slight swelling and tenderness over the left knee. There was no motion in the joint. Wassermann and tuberculin tests were negative. The blood examination showed no abnormal findings. X-ray films showed destruction of the articular surface and beginning ankylosis. There was no evidence of gonococcal infection. The symptoms subsided entirely as ankylosis occurred.

The patient has remained symptomless for 6 years. An operation performed later to secure motion showed chronic inflammation in the joint. The diagnosis was acute infectious arthritis with ankylosis.

CASE 11. A 37-year-old farmer entered the hospital for the relief of pain and limitation of motion in the left knee of 7 months' duration. The onset was gradual, and there was a history of a sprain of the left thigh in lifting a heavy object shortly before.

Examination showed moderate swelling of the knee with slight flexion deformity but no tenderness or increased heat. The physical examination was otherwise negative. The blood was normal. Wassermann, gonococcal-fixation and tuberculin tests were negative. The sedimentation rate was 57 mm. A prostatic smear was negative. Aspiration of the joint showed nothing abnormal. X-ray films of the chest were negative. X-ray examination of the knee showed swelling of the periarticular tissues only. With bed rest and physiotherapy there was a rapid regression of symptoms in 3 months. Chronically infected tonsils were then removed without incident.

The patient has remained completely well for 9 years since discharge. It was the impression of the staff that this was a healed rheumatoid arthritis of the knee associated with a chronic upper respiratory infection, although the possibility of a chronic sprain of the knee could not be excluded.

CASE 12. A 42-year-old storekeeper was admitted complaining of pain and stiffness in the left hip of 8 months' duration. He had lost 10 pounds in weight during the previous 2 months.

Examination showed muscular atrophy, muscular spasm and a 20° flexion deformity at the right hip. There were no other significant findings. Examination of the blood showed a mild hypochromic anemia. The sedimentation rate was 30 mm., and gonococcal-fixation tests were negative. A tuberculin test was positive. X-ray films of the chest showed nothing remarkable. The hip showed a small area of calcification in the body of the ischium, with increased density in the acetabulum. According to the roentgenologist, this was suggestive of tuberculosis. Aspiration of the joint gave no fluid. The serum calcium, phosphorus and phos-

phatase levels were within normal limits. The patient had increasing pain, which was not relieved by traction or a plaster spica.

He was transferred to a tuberculosis sanatorium in his home state, where continuance of severe pain eventually led to an operation on the hip. Examination of tissue from the ischium showed a chondrosarcoma. The patient died 2 months later. The diagnosis was sarcoma of the left ischium.

CASE 13. A 46-year-old housewife had increasing soreness and limitation of motion in the right elbow of 5 years' duration. There was no related history of injury or infection. Her general health had remained good. X-ray examination by the family physician 1 year previous to admission showed bony atrophy about the elbow. A diagnosis of rheumatoid arthritis was made and physiotherapy was given, without relief.

Examination showed a 90° flexion deformity at the right elbow and 5° of painful motion. The elbow was swollen to about twice the normal size and was slightly tender, but showed no increased heat. General examination showed no other significant findings. X-ray examination of the chest was negative. The elbow showed bony atrophy and narrowing of the joint space. The sedimentation rate was 18 mm. Wassermann and gonococcal-fixation tests were negative. The tuberculin test was positive. Fluid aspirated from the joint and injected into a guinea pig showed tuberculosis.

There has been a gradual improvement in the elbow following immobilization and heliotherapy. The diagnosis was tuberculosis of the elbow.

CASE 14. A 61-year-old housewife entered the hospital complaining of pain and stiffness in the right knee of 6 years' duration.

Examination showed moderate swelling and limitation of complete extension in the right knee. It was not tender, and there was no increased heat. The fingers showed Heberden's nodes. X-ray examination of the chest revealed an old tuberculous lesion in the right upper lobe. That of the knee showed narrowing of the joint space, an area of destruction over the femoral condyle and extensive osteoarthritis. The blood was normal. The Wassermann reaction was negative. The sedimentation rate was 94 mm. The tuberculin reaction was positive. The symptoms subsided with physiotherapy and a support for the knee.

The patient remained well for 3 years, when she returned presenting a draining sinus over the knee. Fluid aspirated from the joint and injected into a guinea pig resulted in tuberculous infection. The patient has been at a state tuberculosis sanatorium for the last 2 years. The diagnosis was tuberculosis of the knee.

The experience encountered in these cases has made us more cautious in accepting an immediate diagnosis in any patient with chronic monarticular arthritis. There are no signs or clinical findings that are in themselves pathognomonic of rheumatoid arthritis. If healing occurs gradually, even long observation may not solve the question; likewise, it is difficult to demonstrate a histologic picture in articular tissue that is sufficiently characteristic to establish the diagnosis. In the presence of unrelated infection, chronic trauma—for example, sprain—that has not healed because of inadequate treatment may easily simulate rheumatoid arthritis. Rheumatoid arthritis, as these patients show, rarely remains monarticular, but tends to revert to the usual picture after a few years. Undoubtedly, if the patient remains well, monarticular rheumatoid arthritis may heal and not recur, but this is a rare occurrence. Whether in certain of the patients tuberculosis was superimposed on an already existing rheumatoid or osteoarthritis or whether a quiescent infection was activated by injury or irritation, cannot be decided at the present time. Slow-

growing tumors adjacent to joints may counterfeit chronic arthritis until the further development of the tumor establishes the diagnosis. Hysteria simulating joint symptoms is rare.

In atypical chronic arthritis, particularly when it is monarticular, the diagnosis must be made with caution; in rare cases it cannot be made definitely, long observation helping only to confirm the presumptive diagnosis. Symptomatic treatment is indicated until the diagnosis is established, when other measures directed against the cause of the inflammation can be added. Deformity is prevented by traction, a plaster cast or other appropriate apparatus. When a definite diagnosis has not been made, attempts should be made to promote strength and motion in the joint as the symptoms subside. A number of other therapeutic procedures are useless or positively harmful in certain diseases, and

these should be avoided until a definite diagnosis has been established.

CONCLUSIONS

Chronic monarticular arthritis in which a diagnosis cannot be easily made is infrequent. Often the cause of the inflammation can only be determined by observing the further course of the disease. During this time, treatment must be symptomatic and must be directed to preserving articular function so far as possible. Any procedure that may be harmful should be avoided. No definitive treatment — for example, surgery — should be carried out until the diagnosis has been established. Chronic monarticular arthritis is rarely due to rheumatoid arthritis.

372 Marlborough Street

THE EFFECT OF PENICILLIN ON INOCULATION MALARIA*

A Negative Report

J. A. HINDLE, M.D.,† A. S. ROSE, M.D.,† L. D. TREVETT, M.D.,† AND C. PROUT, M.D.†

BOSTON

UNDER a well-organized national program, clinical and laboratory data showing the therapeutic effectiveness of penicillin in many disease conditions are rapidly accumulating. Re-

laxing tertian malaria in many of the returning troops is proving a definite problem. The chief concern is about the best method for the active treatment of these relapses and about the possibility

FIGURE 1. Charts of Case Receiving Penicillin after the Development of Parasitemia and Fever.

It should be observed that parasites increase and fever occurred in the usual sequence. The malarial course was then altered by the administration of an anti-malarial drug under investigation.

cently penicillin has been made available for more widespread civilian use in certain specified infections. There are few factual data available concerning its efficacy in malaria.

*From the Boston Psychopathic Hospital.

The work described in this paper was performed with penicillin supplied by the Office of Scientific Research and Development. It was done under contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts General Hospital.

†Clinical investigator in the study of penicillin in neurosyphilis and of antimalarial drugs at the Boston Psychopathic Hospital.

that such malarial infestations will form a reservoir for a marked increase in cases among the general population. It is natural, therefore, for questions concerning the effect of penicillin on malaria to arise. It is hoped that this negative report will serve to answer some of these questions.

As a research grant from the Office of Scientific Research and Development for the treatment of neurosyphilis, penicillin was issued to the Boston

Psychopathic Hospital in February, 1944. Simultaneously, a unit for the study of antimalarial drugs was established at this hospital under O.S.R.D. Contract No. OEMcmr-419. Under this double investigative program 28 patients with neurosyphilis have been treated by the combined use of penicillin and benign tertian malaria. In 15 of these cases the two forms of therapy overlapped in such a way as

beginning of fever (101.6°F., rectal), the temperature was taken every hour. Parasite counts, by a slight modification of Earle's method, were performed daily.

RESULTS

The 15 cases in which penicillin and fever therapy were given together are divided into two groups

FIGURE 2. Charts of Cases Receiving Penicillin Several Days before the Inoculation of Malaria.

It should be noted that, after a variable incubation period, increasing numbers of parasites and paroxysms of fever appeared.

to make it possible to draw conclusions concerning the effect of penicillin on this form of malaria. The clinical charts of some of these cases form the basis of this report.

METHOD AND MATERIAL

Penicillin was administered in all cases intramuscularly, 50,000 Oxford units being given every four hours for ten days, a total of 3,000,000 units. Therapeutic malaria was induced by *Plasmodium vivax* (McCoy strain) in all cases. A calculated standard inoculum of 500,000 parasites, taken from an active case, was injected intravenously. The cases were selected, so far as possible, to avoid natural immunity. After inoculation, each patient's temperature was taken rectally every four hours. At the

In Group 1 (6 cases), penicillin was administered after the development of fever and parasitemia. Figure 1 shows the clinical charts of 3 patients. Penicillin caused no reduction in fever, no significant alteration in the timing of the paroxysms and no reduction in the level of parasite counts in any of the cases. These results demonstrate that penicillin does not suppress the clinical manifestations of inoculation *P. vivax* malaria.

In Group 2 (9 cases), penicillin was started before the development of fever. These cases are subdivided into 4 cases in which penicillin was started a few days before the malarial inoculation (Fig. 2) and 5 cases in which it was started at approximately the time of the malarial inoculation (Fig. 3). The clinical charts of these cases demonstrate that

penicillin does not prevent or postpone the development of inoculation *P. vivax* malaria. This seems of special significance, since the number of parasites in the recipient is lowest at the time of inoculation, and if penicillin has any antimalarial action at all, it should have been shown by this experiment.

DISCUSSION

Inoculation malaria differs in certain respects from natural-occurring, mosquito-induced malaria.

In this study only the McCoy strain of *P. vivax* was used. Accordingly, it is not possible to draw definite conclusions concerning penicillin in *P. malariae* and *P. falciparum* infections. If one reasons by analogy to known antimalarial drugs, however, it can be presumed that since penicillin shows no antimalarial activity against *P. vivax* infections, it will have none against the other types.

In a review of penicillin therapy in the United States Army published in December, 1943, Lyons*

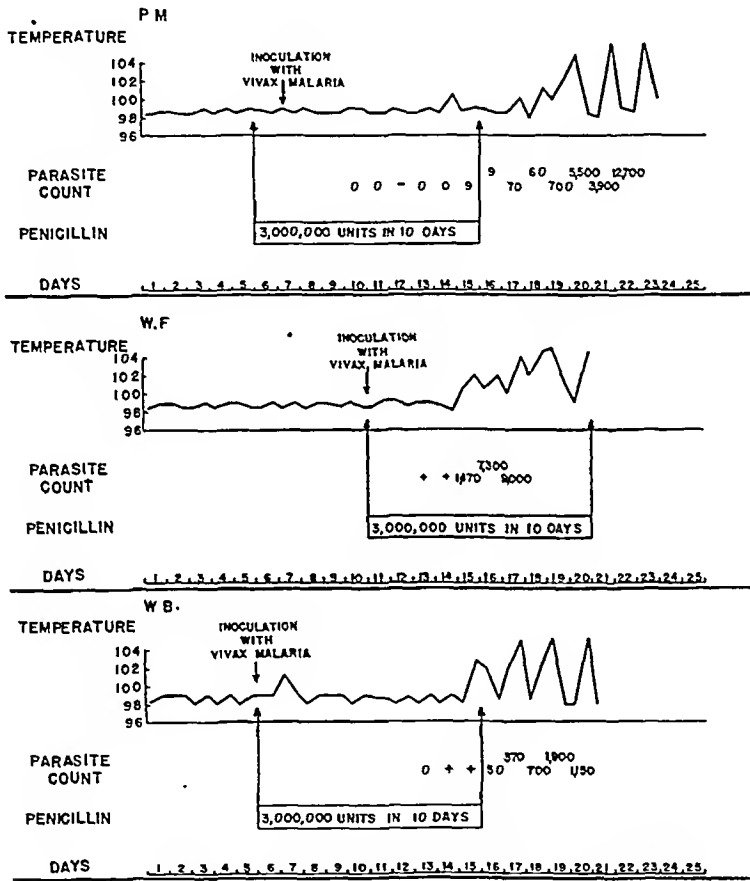

FIGURE 3. Charts of Cases Receiving Penicillin on or about the Same Day as the Malarial Inoculation.

It should be observed that, after a variable incubation period, parasites appeared and increased in number, and paroxysms of fever occurred in the characteristic manner.

It is produced by the transfer of trophozoites from patient to patient. The incubation period is usually shorter by a few days or a week; parasite counts as a rule do not reach quite such high levels; and, although the temperature response may be just as severe as in mosquito-induced malaria, the disease is more satisfactorily suppressed by antimalarial drugs. Cases of inoculation malaria (induced for therapeutic fever) comprise ideal subjects for the testing of drugs with antimalarial activity, for over a period of many years the disease has been well standardized and it has been clearly shown that drugs that do not suppress trophozoite-induced malaria do not suppress sporozoite-induced malaria.

states: "Malaria due to *Plasmodium vivax* is not affected by penicillin. In addition to the 4 recorded failures, 2 other patients have developed recurrent malaria under treatment." No other reference to the effect of penicillin on malaria has been found in the literature.

SUMMARY AND CONCLUSIONS

During investigations on the use of penicillin in neurosyphilis, 28 patients received both penicillin

*Lyons, C. Penicillin therapy of surgical infections in U.S. Army. J. A. M. A 123:1007-1018, 1943.

and benign tertian malaria. Fifteen of these had penicillin administered simultaneously with the malaria. Clinical charts of 9 cases are presented. These charts graphically demonstrate that penicillin does not suppress fever or the parasite count of active inoculation malaria and that when given before or at the time of the malaria inoculation it does not prevent or postpone the development of fever and parasitemia.

It is reasoned by analogy to known antimalarial drugs that since penicillin does not have an antimalarial effect on inoculation *Plasmodium vivax*

malaria, it will not be effective in other types of malaria or in naturally acquired malaria.

Since the writing of this paper we have had further experience in the use of penicillin in therapeutic malaria. In view of the fact that penicillin is rapidly removed from the body, we have tried more frequent injections to exclude this possible loophole in the ineffectiveness of the drug. We have given 3,000,000 units in five days at the rate of 50,000 units at each intramuscular injection every two hours, day and night. This method has been used in about 20 cases without any change in the paroxysms of fever or in the parasitemia.

Addendum. Through an oversight, permission to reprint the two articles "Justice and the Future of Medicine," by Wendell Berge, Esq., and "A Urologist Looks at Changing Trends in Medical Practice," by Dr. Herman L. Kretschmer, which appeared in the November 30, 1944, issue of the *Journal*, was obtained from the editor of the *Journal of Urology* but not from the copyright owner, The Williams and Wilkins Company, Baltimore. Permission has been obtained *ex post facto* and is herewith gratefully acknowledged.

MEDICAL PROGRESS

ORTHOPEDIC SURGERY: THE PROBLEM OF THE INTERVERTEBRAL DISK

CARROLL B. LARSON, M.D.*

BOSTON

THE cause of the backache has for years intrigued orthopedic surgeons. Many popularized diagnoses, such as sacroiliac slip, lumbosacral strain and so forth, represent phases of progress in unraveling the mysteries of back pain. Backache associated with pain in the leg has frequently been inaccurately labeled "sciatica" by doctors and the laity alike. The recent trend is to abolish this term because it carries no accurate connotation concerning either the cause or the distribution of pain. In 1934 a new spark of interest was aroused by Mixter and Barr¹ when they introduced the syndrome ascribed to herniation of the nucleus pulposus. A profusion of literature attests to the popularity of this new syndrome, variously referred to as ruptured intervertebral disk, protruded disk and herniation of the disk. The purpose of this report is to give a concise notion of the factual information, as well as the controversial opinions, that exists regarding the intervertebral-disk syndrome as it is known today.

The embryologic development of the spine, with special reference to the intervertebral disk, has been studied by Ehrenhaft,² and the point he emphasizes is the avascularity that occurs in the disk after the age of twenty-five. Possibly this has a bearing on the etiology of pathologic disks. The question of trauma as the cause of rupture of the intervertebral disk remains unsettled. Hyndman, Steindler and Wolkin³ are inclined to believe that even in the few patients who describe the root pain as being coincident with the back injury there has been a preceding back injury. Inman and Saunders,⁴ in a detailed account of the anatomy of the intervertebral disk, point out the frequency of protruded disks in the region on the intervertebral foramen, where the postligamentous support between vertebral bodies is weakest. They estimate, by an analysis of force vectors resultant upon the lower lumbar disks in lifting a weight of 50 pounds, that, under average conditions, a pressure amounting to about 500 pounds is exerted. In addition, when the spine is flexed, the nucleus pulposus in the lumbar region migrates dorsally, tension is thrown on the posterior portion of the annulus, and if some rotation accompanies flexion, the annulus is further subjected to torsional stresses. These forces alone can cause herniation. If a single injury results in herniation, it presupposes a considerable tear in the tough annulus fibrosus. At operation the

posterior ligament frequently is found intact, but when incised reveals a loosened free portion of dense fibrous tissue that must be as much a part of the annulus as of the nucleus pulposus. These cases make one wonder whether some type of pre-existing degeneration is responsible for the separation of a fragment. At present there are many unanswered questions pertaining to the pathogenesis of the protruded-disk syndrome.

Young and Brailsford⁵ carefully followed 497 patients with backache and give a numerical notion concerning the relative frequency of ruptured disks. These figures were taken from a clinic in which both soldiers and industrial workers were cared for. Of the total number, pain was localized in the back in 206 cases, was associated with referred leg pain in 204 cases and was associated with referred trunk pain in 87 cases. One hundred and three soldiers with leg pain were studied for the presence of a ruptured intervertebral disk. Of these cases, laminectomy was performed in 15; 9 cases showed definite protrusion, 2 cases had a thickened ligamentum flavum, and in 4 cases no abnormality was found. These figures tend to indicate that in all cases with referred pain in the leg approximately 10 per cent will prove to be due to ruptured disks.

The exact cause of the pain in the disk syndrome has not been clearly established. The evidence suggests direct nerve-root pressure as a major source of radiation pain in the many patients who have had relief of pain after removal of the mass. In view of the fact that many patients are not relieved of this pain following operation, one must always keep in mind other mechanisms of pain production. Such mechanisms must explain the leg pains in cases in which exploration has failed to reveal a protruded disk, as well as similar leg pains in a large group of other conditions, such as ligamentous injuries, fractured facets, hypertrophic overgrowths, impinging spinous tips, unstable lumbosacral junctions associated with various congenital anomalies, arachnoiditis, malignant neoplasm, infectious lesions, rheumatoid arthritis and sacroiliac strain.

Steindler et al.³ have shown that referred pain can be completely eliminated by interrupting a reflex arc. He has traced the reflex pathways that connect the lesion to the so-called "trigger points of localized sensitivity," as well as to the referred pain in the leg. These pathways can be interrupted by an injection of novocain into the trigger point or points. From a practical standpoint he has been able to relieve pain in about one fifth of the cases

*Instructor in orthopedic surgery, Harvard Medical School; assistant in orthopedic surgery, Massachusetts General Hospital.

of referred pain in which the cause was other than a protruded disk.

Intervertebral disks have been shown to contain nerve fibers.² This makes it possible for the pain to arise within the disk space, particularly when the disk is subjected to excessive pressure or when it is the seat of degenerative disease. Inman and Saunders⁴ were struck by the clinical findings in cases of protruded disks, inasmuch as the areas complained of by the patients were quite similar, whether the protrusion was causing pressure on the fourth or fifth lumbar or first sacral nerve root. This led them to adopt a new sclerotome, rather than dermatome, distribution of referred-pain areas. The reader is urged to read the original article in order to comprehend completely this feasible conception.

The idea has many times been expressed that any backache associated with radiation pain into the thigh or leg is due to a ruptured disk. Certainly one should look carefully into the history for more distinguishing features of a ruptured intervertebral disk. Many cases with a presumably classic history of a protruded nucleus have, on exploration, revealed no findings to substantiate the diagnosis. On the other hand, explorations have revealed ruptured disks to account for local pain in the back, as well as motor and sensory disturbances, without pain in the thigh or leg. The above facts suggest that a "classic history" is nonexistent. The history should give clearly the onset, course, type and distribution of the pain, as well as associated phenomena, such as paresthesias, motor weaknesses and so forth. Statistically, however, there are no symptoms, individual or in the aggregate, that occur with great enough frequency to be considered pathognomonic. In general, the outstanding symptom is pain. This is usually recurrent in the back, with eventual radiation into the posterolateral thigh, the lateral calf and the outer side of the ankle. It is relieved only partially by changes of position, especially those in a direction of spine flexion. Aggravation usually occurs during sneezing or coughing, and is caused by sudden motions, especially those of extension. Paresthesias, when present, are described as numbness or coldness and are not stationary. Motor weaknesses occur in a small percentage of cases and, when present, are continuous. A history of trauma has been reported in from 30 to 60 per cent of cases.

No attempt has been made to separate the symptoms of a bulging unruptured disk from those of a free loose fragment or of a simple unstable disk. This may become important as we learn more about the indications for treatment. At present, so few of the fundamentals regarding the pathogenesis of symptoms are known that only by clarification of these fundamentals can one hope to be more specific.

What has been said about a lack of knowledge to explain symptoms can be applied equally well to the findings on physical examination. In general

the lumbar spine is held in flexion and a list is present. Motion of the lumbar spine is limited in all directions, but mainly in extension and lateral bending toward the side of the pain. Straight-leg raising reproduces the pain at a low level. A positive jugular-compression test, paresthesias, muscular weakness and a diminished to absent ankle or knee jerk on the affected side may or may not be present. When the last is present, it strongly suggests the presence of nerve-root pressure. With present understanding of the problem, no one point of history or no one physical finding is pathognomonic of a ruptured disk. A combination of all the facts of the history and all the physical signs should lead the examiner to look for further corroborative evidence, in order to make an accurate diagnosis.

Logically, one looks to x-ray methods for the demonstration of a space-occupying lesion in the spinal canal. Because of the failure of earlier methods, such as air myelography, to be convincing in the majority of cases, substitute methods are being tried. Lipiodol, used according to the method of Kubik,⁶ is popular, and most of the oil can be withdrawn by an experienced person. Pantopaque, a thinner oil that maintains a good column, is gaining in popularity as a contrast medium. Substances such as Thorotrast give a less dense shadow, through which midline disks can be visualized,⁷ but because of definite dangers, the advantages probably do not exceed the risk of its use. Spurling⁸ has been able to localize clinically the level of the protruded disk in 60 per cent of his cases, but in the 40 per cent in which doubt existed, he resorted to the use of Pantopaque. It is well known from surgical exploration that protruded disks are found in cases in which the x-ray films were negative; conversely, protrusions are not always found in cases in which the films were positive. Horwitz⁹ has emphasized the discrepancy between x-ray and operative findings. Degenerative disk disease, overgrowths of articular facets and the normal bulging of an overlying ligamentum flavum, by virtue of its anatomic arrangements, are potent causes of defects in the contrast column that can be mistaken for disk fragments. When the contrast medium allows good lateral visualization of the spinal canal, the above-mentioned defects are seen to lie posteriorly and can thereby be more accurately interpreted.

Before leaving the subject of x-ray diagnosis, the value of bone films should be mentioned. Scott¹⁰ has reviewed in detail the radiography of facets, bony overgrowths and fractures, all of which enter into the differential diagnosis. Such films should be a routine part of every back examination.

A narrowed intervertebral space as observed in x-ray films is of no consistent diagnostic value. Vinke and White¹¹ have conclusively shown that narrowing occurs congenitally, and this condition has been observed frequently as an incidental x-ray finding during examination for symptoms other

than those referable to the spine. Ver Bruggen,¹² reporting the end results in 66 cases of herniated disk found narrowing of the space in only 30 per cent of the cases. Stump and Narius¹³ reported an interesting observation in a patient with meningitis who responded to therapy but who subsequently had severe low-back pain without radiation. X-ray films revealed loss of disk space between the fourth and the fifth lumbar vertebra, without fever to indicate active infection, and the authors concluded that repeated lumbar punctures at that level had entered the interspace and had precipitated a degeneration.

From the foregoing, it is obvious that positive criteria for the diagnosis of a ruptured intervertebral disk are lacking. When the history and examination are suggestive of a protruded disk, bone x-ray films should exclude such possibilities as gross fracture, malignant neoplasm, infection or generalized bone disease. Myelography should be done to show the presence of a space-occupying lesion in the spinal canal, as well as the level or levels of the lesion. An elevated total-protein level in the spinal fluid is helpful, Ver Bruggen¹² having stated that good results from the removal of a ruptured disk can be anticipated in cases in which the total protein is over 40 mg. per 100 cc. The final diagnosis at times can be made only by exploratory laminectomy. This method of diagnosis should be reserved for the cases in which the severity of the pain justifies the operation.

When a diagnosis of ruptured disk has been made, the method of treatment must be selected. End-result study is the only available means of determining the effectiveness of treatment. Sufficient end results have not been reported to draw definite conclusions. Bradford¹⁴ has reviewed the technical advances of operative removal, but stresses a pre-operative period of conservative treatment, as does Pilcher.¹⁵ If the pain is intractable and refractory to conservative treatment, this fact in itself has been offered as evidence in favor of the diagnosis of ruptured disk, and also as an indication for operation.

Poppen's¹⁶ technic for removal of the ruptured disk represents the commonly accepted type of hemilaminectomy and extradural approach. Spinal fusion has frequently been combined with the removal of the disk in cases in which there is evidence to suggest instability of the spine. No information is available to intimate the number of cases in which fusion has been done, but it is apparent that such an operation is indicated for continued disability after simple removal of a protrusion.

The final chapter either in the diagnosis or in the treatment of ruptured intervertebral disks has not yet been written. Only by a continued careful analysis of cases and by an honest appraisal of their end results can the data necessary to produce the answer to the present questions be accumulated.

CASE 31051

PRESENTATION OF CASE

A forty-nine-year-old married woman was admitted to the hospital with a palpable mass in the upper abdomen.

The patient had been in good health until three months prior to admission, when she developed a mild ache in the midportion of the back. This was followed in a few hours by a rather diffuse, nonradiating ache in the epigastrium, accompanied by nausea. On one occasion she vomited undigested food recently eaten. There was no hematemesis, jaundice or change in bowel habits, and the stools were of normal appearance. After three days the symptoms completely disappeared. The physician whom she consulted, however, felt a mass in the epigastrium. About two months prior to entry an x-ray examination revealed an "ulcer of the small intestine." At that time the mass was thought to be smaller on palpation. She continued to feel well, with an excellent appetite, and had no recurrence of symptoms, but because of the persistent mass was finally admitted to the hospital for study.

Three years before entry she had undergone a hemorrhoidectomy, with excision of an anal fistula. Her menstrual periods had been regular until five months prior to admission, when she developed amenorrhea, interrupted only by a scanty one-day period about a month before entry.

Physical examination revealed a well-developed and well-nourished woman in no discomfort. The lungs were negative except for some decrease in tactile fremitus over the left apex. The heart was negative. A firm, smooth, nontender, nonpulsating mass was palpable in the epigastrium; it was movable and shifted with respiration. No continuity with any abdominal organ could be demonstrated.

The temperature, pulse and respirations were normal. The blood pressure was 128 systolic, 75 diastolic.

Examination of the blood showed a white-cell count of 8700, with 73 per cent neutrophils, 19 per cent lymphocytes, 7 per cent monocytes and 1 per cent eosinophils. The urine had a specific gravity of 1.020, with a + test for albumin; the sediment

contained a few white cells per high-power field. A stool examination was negative. A Hinton test was negative.

A gastrointestinal series revealed an esophagus that was slightly wider than normal. There was no definite evidence of varices. The stomach was rather long and large, and the lesser curvature in the region of the antrum and lower body revealed a large extrinsic pressure defect (Fig. 1). The duodenal cap and second portion of the duodenum were displaced laterally and also showed evidence of extrinsic pressure. A barium enema revealed no abnormalities. An intravenous pyelogram revealed normal kidney outlines, prompt dye excretion and normal urinary passages.

On the seventh hospital day a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. GEORGE W. HOLMES: Before taking up the x-ray findings in this case I should like to go over the history briefly. I think it is quite important for a radiologist to know something about the history of a patient before he attempts examination, because, unless he does, he is likely to leave out of the examination some of the most significant procedures. I shall therefore approach this case as I think a radiologist should.

The first points of importance are the age of the patient and the duration of the illness. This woman was nearly fifty and she had trouble three months prior to coming into the hospital. There is no reason to suppose that the presenting mass had been there prior to the onset of the symptoms that are described. It was a sudden onset—a mass appeared and all the symptoms disappeared. If it had not been for the mass the patient would not have sought medical advice. The record states that she had an "ulcer of the small intestine." That is a peculiar statement, and I assume that it was made by the patient; a radiologist would probably have specified where the ulcer was. I am inclined to discard the statement as being of no particular value. We should not put too much weight on anything that we have not ourselves observed or proved.

The history also states that she had an anal fistula. I was taught that that can be of tuberculous origin, and to look for tuberculosis elsewhere in the body.

She had amenorrhea, which does not suggest much to me because of her age. I should like to ask Dr. Linton if he would pay any attention to the fact that a woman of this age was not menstruating.

DR. ROBERT R. LINTON: None whatever.

DR. HOLMES: The next point of significance is the character of the mass. On physical examination it was firm, smooth and nontender and did not pulsate; it was movable and shifted with respiration. I consider these observations to be quite important.

*On leave of absence.

The fact that the examiners could not connect it with any particular organ is of little significance.

Among the conditions one has to consider, of course, is an aneurysm. Although pulsation does not prove that a lesion is an aneurysm, the absence of pulsation is of great value. The temperature, pulse, respirations and blood pressure were normal.

I should say that it was ruled out by that method and shall not waste any time on it.

In the examination of the gastrointestinal tract there are several significant things. First is the pressure defect on the lesser curvature of the stomach, which extends into the duodenum and seems to lie nearly in the midportion of the abdomen. The

FIGURE 1

The examination of the blood I also consider to have been within normal limits. Is that true?

DR. LINTON: Yes.

DR. HOLMES: Is there anything in the blood picture to cause a suspicion of lymphoma? That is one of the things that I want to consider.

DR. LINTON: I should think not.

DR. HOLMES: The attending physicians evidently wanted to rule out the urinary tract as a possible source for this mass. Here is the series of films, and

density of the shadow is about the same as that of muscle or liver. There is no shadow of diminished or increased density, which would be of some value. I can make out the liver quite well; it is not enlarged or abnormal in shape, and the abstract tells us that the patient had no esophageal varices. There is nothing suggestive in the small or large bowel. The location of the mass is of some importance: it is above the lesser curvature and rather well over toward the midline. I shall go over these points in detail later.

On the seventh hospital day a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. GEORGE W. HOLMES: Before taking up the x-ray findings in this case I should like to go over the history briefly. I think it is quite important for a radiologist to know something about the history of a patient before he attempts examination, because, unless he does, he is likely to leave out of the examination some of the most significant procedures. I shall therefore approach this case as I think a radiologist should.

The first points of importance are the age of the patient and the duration of the illness. This woman was nearly fifty and she had trouble three months prior to coming into the hospital. There is no reason to suppose that the presenting mass had been there prior to the onset of the symptoms that are described. It was a sudden onset — a mass appeared and all the symptoms disappeared. If it had not been for the mass the patient would not have sought medical advice. The record states that she had an "ulcer of the small intestine." That is a peculiar statement, and I assume that it was made by the patient; a radiologist would probably have specified where the ulcer was. I am inclined to discard the statement as being of no particular value. We should not put too much weight on anything that we have not ourselves observed or proved.

The history also states that she had an anal fistula. I was taught that that can be of tuberculous origin, and to look for tuberculosis elsewhere in the body.

She had amenorrhea, which does not suggest much to me because of her age. I should like to ask Dr. Linton if he would pay any attention to the fact that a woman of this age was not menstruating.

DR. ROBERT R. LINTON: None whatever.

DR. HOLMES: The next point of significance is the character of the mass. On physical examination it was firm, smooth and nontender and did not pulsate; it was movable and shifted with respiration. I consider these observations to be quite important.

*On leave of absence.

DR. ALLEN: Yes; a great deal more so than a pancreatic cyst, which would move only with expiration.

DR. SWEET: This was not so movable as one would expect for a mesenteric cyst; nor did it move so much as the one large hepatoma of the liver that happened to have had and that was presented here two or three years ago.¹

DR. HOLMES: If this was a mesenteric cyst it must have been in the lesser omentum. I do not believe that a cyst in the greater omentum or in the mesentery of the bowel could have produced such an extensive pressure defect in the stomach.

CLINICAL DIAGNOSIS

Tumor of liver ?
Cyst of pancreas ?

DR. HOLMES'S DIAGNOSIS

Cyst, probably in tail of pancreas.

ANATOMICAL DIAGNOSIS

Islet-cell adenoma of pancreas.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Will you tell us about your operative findings, Dr. Sweet?

DR. SWEET: I should like to say first that Dr. Holmes certainly made an excellent clinical analysis of this case, far better than we did. I decided that it must be a tumor of either the liver or the pancreas. At operation the mass was obviously in the pancreas. It moved with the pancreas the way a carcinoma of the stomach does when it is adherent to the pancreas. The tumor was not pedunculated and could be moved only by moving the entire pancreas; it was part of the body of the pancreas, being located just to the left of the head, close to the duodenum. It was vascular and appeared to be a solid tumor or, if a cyst, an extremely tense one. It was somewhat of a technical stunt to get it off the middle colic vessels without destroying the vascular supply of the duodenum, but it came out, leaving a great hollow in the pancreas. I had never seen anything like it before.

DR. CASTLEMAN: As Dr. Sweet indicated, the specimen we received was circumscribed, with a fairly smooth surface. It was distinctly brownish and, on section, soft and not at all cystic. Microscopic examination showed it to be an adenoma of the islet cells of the pancreas, which apparently had not produced any endocrine disturbance. We went back and questioned the patient about hypoglycemic spells but were unable to elicit any suggestion of one. In Whipple's² review of these tumors, he found that the number that were asymptomatic was greater than that of those producing hypoglycemic symptoms.

DR. HOLMES: Was there any evidence of hemorrhage into the tumor?

DR. CASTLEMAN: No.

CASE 31052

PRESENTATION OF CASE

A thirty-one-year-old married woman was admitted to the hospital with abdominal cramps.

One month prior to admission the patient missed her expected menstrual period. Four to five days later she began to have vaginal bleeding, passing fresh blood and dark shreds on the first day, followed by intermittent spotting. Her breasts had enlarged and were tender. Twenty-four hours before entry she developed severe cramps in the upper portion of the abdomen. These were quite severe during the night and interfered with sleep. There was no nausea, vomiting, chills, fever or diarrhea. She had had a normal bowel movement on the day prior to admission but none since.

The patient had been admitted to the hospital ten years previously with abdominal cramps. A laparotomy performed at that time revealed a third degree retroversion of the uterus and chronic typhilitis. A ventral suspension of the uterus was done, and the appendix was removed.

She had been married two other times, followed by divorce. During her first marriage eight years previously she had one pregnancy, which was aborted. There were no other pregnancies.

Physical examination on admission revealed a well-developed and well-nourished young woman. The breasts were moderately enlarged and tender, with a widened areola. The heart and lungs were negative. The abdomen revealed diffuse tenderness without spasm but with moderate rebound tenderness in both lower quadrants. No masses were felt. Peristalsis was normal. Pelvic examination revealed a soft uterus of normal size. The fundus was in anterior position and freely movable. The cervix was moderately soft. An irregular, slightly tender mass, 3 to 4 cm. in diameter, was felt in the right adnexal region.

The temperature was 99.8°F., the pulse 66, and the respirations 20. The blood pressure was 110 systolic, 56 diastolic.

Examination of the blood revealed a white-cell count of 13,500. The hemoglobin was 11.8 gm. The urine was essentially negative. A stool examination was negative. A Friedman test for pregnancy was positive.

A roentgenogram of the abdomen revealed an unusual distribution of gas, there being a consider-

Could this patient have had an abdominal aneurysm? There is no sign of arteriosclerosis. The Hinton test was negative, and the tumor did not pulsate. I believe I can drop that. In considering a case, one should always keep in mind the factors that are of interest to the patient. In this particular case the patient wanted to know if she had a lesion that ought to be operated on, and, if so, whether it was going to be a great risk. So we have to rule out aneurysm on that basis; if on no other.

Could she have had a tumor of the liver? It is in the proper place, and it is smooth, round and not lobulated, but she had no varices or signs of cirrhosis; also, there is no evidence of metastases elsewhere in the body. The absence of change in the liver and the absence of esophageal varices make the diagnosis of primary tumor of the liver unlikely. If I had seen this patient on the ward and was making my interpretation from the evidence that we have here, I should say that she did not have a primary tumor of the liver, but at this conference, where many of the rare cases are selected for discussion, this case might be the exception; I do not believe that I can rule out a tumor of the liver.

Could it have been a tumor of the pancreas? It might well have been. The mass is smooth and round and probably cystic. A cyst of the pancreas is not too infrequent. Ordinarily it occurs in the head of the pancreas and does not produce this type of deformity; but occasionally it does. It is not particularly uncommon for tumor in the tail of the pancreas to produce this sort of picture. The duodenum is displaced to the right and downward, and the duodenal loop, instead of being enlarged, is much smaller than it should be. Tumor of the head of the pancreas usually increases the size of the loop rather than diminishes it, but tumor of the tail may not. Therefore, I believe that that is a likely diagnosis. Can tumor of the pancreas cause as few symptoms as this patient had? And is it consistent with the symptoms that she did have? Can you help me on that, Dr. Sweet?

DR. RICHARD H. SWEET: If it were a cyst, I should think so.

DR. HOLMES: Could this have been hydrops of the gall bladder? It is in the correct place. I should expect a hydrops of the gall bladder to displace the whole duodenum downward, but it looks a little too far to the left. But I do not see how I can rule that out on the evidence that we have. Could one have hydrops of the gall bladder with absence of symptoms?

DR. SWEET: I doubt it.

DR. HOLMES: I hope that Dr. Sweet and Dr. Linton are helping me. I have been accused of not helping the surgeons at times.

Could it have been a lymphoma? Lymphomatous masses or a single mass does occur in the belly. Was a careful search made for enlarged lymph nodes elsewhere in the body?

DR. BENJAMIN CASTLEMAN: None were found.

DR. HOLMES: The blood picture was normal. Furthermore, a lymphoma usually is not so round as this mass; it is apt to be lobular. I am going to rule it out on that basis.

On account of the anal fistula, I have to think of tuberculous nodes. There is no calcification in the tumor, and no other calcified nodes are seen elsewhere. I believe that we can rule it out.

We come down to some form of cyst — a cyst in the lesser omentum, a cyst of the pancreas, a dermoid cyst or an echinococcal cyst. Dermoid and echinococcal cysts are likely to contain calcium, but there is no evidence of calcification in this tumor. In addition, the appearance of the lesion and the story make echinococcal cyst seem unlikely. What part of the country did the patient come from?

DR. CASTLEMAN: New England.

DR. HOLMES: Echinococcal cysts are rare in persons who have not been outside New England.

There are two or three things that should have been done during the x-ray examination, provided the radiologist had all the facts that I have. For instance, if this were a dermoid cyst and the patient had a film taken in the upright position, the contents of the cyst might have settled in different layers. Furthermore, there should have been an x-ray examination of the chest to be sure that she did not have metastases. That would help in deciding whether the tumor was benign or malignant.

This could have been a leiomyosarcoma arising in the wall of the stomach. In that case, a careful search for metastases in the lung would have been helpful, as well as an examination in the upright position to see whether the mass could be separated from the stomach. A leiomyosarcoma would be adherent to the stomach, whereas a cyst in the pancreas would not. They may have done all this of course; but there is no record of it.

In conclusion I shall make the most obvious diagnosis, that is, a cyst, probably in the tail of the pancreas. I cannot be absolutely certain that it was not a primary tumor of the liver, but in the absence of cirrhosis of the liver this is extremely rare.

DR. ARTHUR W. ALLEN: I should like to call attention to a sign that Dr. Lincoln Davis discovered several years ago in diagnosing echinococcal cysts. He found that on percussion it gave the same sensation that one would get on percutting an inner spring mattress. This abstract says nothing about percussion, and that might have helped to rule out one possibility.

DR. SWEET: I did not percuss it.

DR. ALLEN: Another interesting feature is that the mass was described as movable and shifting with respiration. It does not say how movable; that would be helpful in differential diagnosis because cysts arising in the mesentery are quite movable.

DR. HOLMES: Would a cyst in the lesser omentum be movable?

case the decidua was so abundant that we seriously considered a diagnosis of uterine pregnancy. The absence of any trace of a chorionic villus, however, should make one suspect some sort of ectopic pregnancy.

In the gross specimen there were, as Dr. Simmons has stated, fibrous nodules near the cornua of the uterus—a condition that has been called “salpingitis isthmica nodosa.” On microscopic examination there were islands of epithelium in gland formation, although they were probably not true glands but pseudoglands. The ordinary explanation of this condition is that some inflammatory process has occurred in the fallopian tube with the formation of a great deal of connective tissue, which pinches off the tortuous epithelial folds, so that they appear as acini in the walls of the tube. Perhaps that is the best explanation for most of these cases. In a recent paper, however, Schenken and Burns,¹ who made serial sections of the entire tube, state that they believe that these little islands of epithelium are not entirely the result of infection

but often due to diverticulosis of the tube, with or without inflammation.

Another explanation of salpingitis isthmica nodosa is that it is endometriosis of the fallopian tube. The glands are similar to the endometrium, but there is no stroma present and most of these patients do not have endometriosis elsewhere.

DR. SIMMONS: It is difficult for me to conceive how this patient could have become pregnant, although Dr. Meigs² has described one case of pregnancy in a patient with bilateral salpingitis isthmica nodosa. It must be extremely rare. In most textbooks of gynecology the lesion is described as being due to gonorrhea, tuberculosis or adenomyosis.

DR. CASTLEMAN: Those are the usually accepted causes, but the suggestion of Schenken and Burns that it may be due to diverticulosis is intriguing.

able amount in the transverse and descending colon but little in the small bowel and stomach.

On the eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS M. INGERSOLL: As I start my discussion there is one premise that I think I shall have to assume, namely, that this patient was pregnant. Certain facts pointing toward it cannot be refuted. The history is compatible. She had a positive Friedman test, and the physical examination also bears out that diagnosis. There are two things that bothered me after reading the case report and that did not seem to fit in with anything that I could think of as a diagnosis. One was that at the time of admission she had severe cramps in the upper abdomen. In my experience that does not fit in with any condition in the pelvis related to a normal pregnancy. The other thing was that I cannot explain the x-ray findings on the basis of pregnancy.

DR. BENJAMIN CASTLEMAN: Dr. Holmes's comment was that reversed peristalsis of the colon at the time the films were taken might have produced such an appearance.

DR. INGERSOLL: Then from the x-ray examination I believe that I shall have to rule out any lesion in the small or large bowel.

The differential diagnosis concerns whether the patient had an extrauterine pregnancy or an intrauterine pregnancy with a threatened miscarriage or an incomplete abortion. Extrauterine pregnancies are relatively frequent, 1 out of every 300 gravid women having one. The setup here is excellent for an ectopic pregnancy. This woman had been married three times and had had one abortion and possibly pelvic inflammatory disease, all of which is an excellent cause for an extrauterine pregnancy. So the first possibility that comes to me is that this mass that was felt in the abdomen was due to an ectopic pregnancy, possibly in the tube. It might have been one of the rare pregnancies that occur in the ovary, the ovum being fertilized just as it is discharged from the ovary, with implantation taking place there. It is possible that the patient had a tubal abortion at the time of the severe pain and that the ovum was outside the tube and actually attached to the large bowel, irritating it and causing a reflux of gas back into the transverse colon, as Dr. Holmes described.

The possibilities other than extrauterine pregnancy are those associated with an incomplete miscarriage. For example, she could have had an incomplete miscarriage to account for the way the uterus felt, and the mass that was felt on the right side could have been inflammatory, — a tubo-ovarian abscess, — although it is quite rare to have a patient with both pregnancy and a real abscess in the tube and ovary. The right-sided mass might have been

an endometrioma; she was thirty-one years of age and had never had a full-term pregnancy. The other thing that occurred to me is that this patient might have had a normal intrauterine pregnancy together with a small cyst of the ovary that had twisted, thus destroying the corpus luteum and producing a miscarriage.

In summary, I shall say that the patient was pregnant and that either the pregnancy was ectopic or she had an incomplete miscarriage, with some other associated phenomenon. If I had to commit myself to one diagnosis, it seems to me that this whole case fits in best with an extrauterine pregnancy, and since this is a clinicopathologic case, in which one expects the unusual, I shall postulate that the extrauterine pregnancy was implanted on the ovary.

DR. FRED A. SIMMONS: The patient was sent to me by an obstetrician because of sterility; she had been married to her third husband for three years. The first time that I examined her, there was a mass on the right side, but it did not change in the subsequent five or six weeks. It took a long time to convince me that it was a tubal pregnancy. At the first visit to the office her menstrual period was a day or two overdue and I assumed that she was pregnant. Following amenorrhea for eight or ten days she then started to flow. Since I thought it was a normal pregnancy, I tried to maintain it by bedrest and so forth. Then when she developed cramps, I sent her into the hospital.

On the fourth hospital day she passed a piece of tissue 1 cm. wide and 4 cm. long, which I immediately assumed was produced by conception. It was sent to the laboratory, where a diagnosis of decidua without chorionic villi was made, which means ectopic pregnancy.

CLINICAL DIAGNOSIS

Tubal pregnancy.

DR. INGERSOLL'S DIAGNOSIS

Ectopic pregnancy, possibly in ovary.

ANATOMICAL DIAGNOSES

Tubal pregnancy.

Salpingitis isthmica nodosa, bilateral.

PATHOLOGICAL DISCUSSION

DR. SIMMONS: The patient was operated on, and we found a tubal pregnancy on the right. She had in addition a lesion in the isthmus of both tubes that grossly suggested salpingitis isthmica nodosa.

DR. CASTLEMAN: How much blood did she have in the peritoneal cavity?

DR. SIMMONS: About 40 cc.

DR. CASTLEMAN: One interesting point, which Dr. Simmons mentioned, is the presence of decidua in the uterus in cases of ectopic pregnancy. In this

medicine is being subjected to criticism. Every member of the Massachusetts Medical Society should do all within his power in an attempt to bring about the defeat of these bills.

A NEW AND RAPID LABORATORY TEST FOR SMALLPOX

MAJOR VAN ROOYEN and Major Illingworth,¹ of the Royal Army Medical Corps, have recently contributed what appears to be a most valuable laboratory test for smallpox. According to them, a smear preparation from a suspected case of smallpox can be made, stained and examined and the report handed to the physician in half an hour. The material is obtained by delicately scraping either the base of a vesicle or, still better, an early papule without drawing blood. This is rubbed onto a specially prepared slide, stained according to the Paschen method (which is described in detail) and examined under the microscope. If the material was secured from a case of smallpox, the trained eye quickly detects masses of characteristic elementary bodies. Not only are these infinitely more numerous than the elementary bodies found in chicken pox² but they are about twice as large. The authors warn that this method applies only to the identification of smallpox bodies and is not applicable to those of chicken pox, since the latter are too scanty.

The test was positive in 77 cases of smallpox and negative in only 3. In no case did a positive test disagree with the clinical diagnosis. The test proved particularly valuable in the early diagnosis of cases of modified smallpox, in which only a few discrete lesions, suggestive of chicken pox, were present and also in the early stages of the severe forms of hemorrhagic smallpox in which the papular stage suggested typhus fever or measles. Indeed, in the latter type of case the earliest buccal lesions often resembled Koplik spots. The importance of this test can best be appreciated by realizing that the Paul test, in which infective material is scratched into a rabbit's cornea, can only be completed in three days and that the same applies to the chick chorioallantoic-membrane test, whereas the floccu-

lation test is not reliable until after the first week of the disease.

In another contribution Major Illingworth and Major Oliver³ report their observations on an epidemic of smallpox in Egypt during 1943 and 1944. These authors emphasize that the early clinical differentiation of smallpox and chicken pox was often impossible. Not only was the typical distribution of the lesions ("centrifugal" and "centripetal," respectively) a snare and a delusion, but they also found that smallpox lesions came out in crops over a period of four or five days, a characteristic usually ascribed to the lesions of chicken pox, and that maturation of the lesions was sometimes quite as rapid in smallpox as in chicken pox. They noted oval lesions in the folds of the skin and petechiae in the axillas in cases of the hemorrhagic type. Even the characteristic backache of the prodromal stage of smallpox was by no means a prominent symptom. Finally, 96 of the 100 patients in the series had been previously vaccinated, 70 having been vaccinated "successfully" within two years.

All this goes to show that there are exceptions to every point of differentiation between smallpox and chicken pox, as was brought out in a recent progress review in the *Journal*.⁴ Smallpox varies in character and severity in different localities. Under wartime conditions as they exist today in Egypt, with the influx of troops from so many parts of the world, this disease in almost every hue of human skin presents extraordinary difficulties. Faced with these, the authors found that examination of the scrapings from papules or vesicles for elementary bodies was of the greatest assistance in making an early diagnosis.

STANDARDS OF MEDICAL EDUCATION

ON JANUARY 5, 1945, the failure of the Massachusetts Approving Authority to accredit the Middlesex University School of Medicine was upheld by the Superior Court of Suffolk County.

The law establishing the Approving Authority was signed by the Governor of Massachusetts, James M. Curley, in 1936. A photograph taken at the time he signed the bill shows several members of the Massachusetts Medical Society watching the proceedings with great interest, among them being Dr. Charles E. Mongan, who at that time was president of the Society and had much to do with the campaign to enact the legislation. Also in the group was the present dean of the Middlesex University

School of Medicine, Dr. Stephen Rushmore, who then was secretary of the Board of Registration in Medicine and automatically became a member of the Approving Authority.

Soon after its establishment, the Approving Authority drew up the seventeen qualifications that a medical school must meet in order to be approved. These qualifications are the same as those used to measure the quality of the schools that have recently applied for approval, and it was the failure of the Middlesex University School of Medicine to meet all the qualifications that made it necessary for the present Approving Authority to deny approval. This denial followed three inspections by three different groups comprising the Approving Authority and a public hearing held in July, 1944.

The law passed in 1936 stated that students who matriculated at a medical school on or after January 1, 1939, must graduate from a school accredited by the Approving Authority in order to be eligible to take the examination for registration in this state. The law was amended in 1939, the effective date being changed to January 1, 1941. Students coming under this classification began to graduate from medical schools during the summer of 1944, and those who had received their diplomas from schools not approved by the Approving Authority have been denied the right of examination by the Board of Registration in Medicine. Massachusetts has three such schools, namely, the Middlesex University School of Medicine, the Massachusetts College of Osteopathy and the College of Physicians and Surgeons. The last two have never asked for approval.

At long last the practice of medicine in the Commonwealth is open only to those men and women who have been properly trained, and Massachusetts need no longer be called "the dumping ground" for medical-school graduates; but a number of bills that aim either to abolish the Approving Authority or to postpone again the date of its effectiveness have already been introduced for the consideration of the present session of the General Court. The passage of such legislation can either halt or stop forever the progress toward higher medical standards, and high standards of medical education *must* be maintained in these days when the practice of

THE DIAGNOSIS OF POSTERIOR HERNIATION OF THE LUMBAR INTERVERTEBRAL DISKS*

DONALD MUNRO, M.D.†

BOSTON

IT IS common knowledge that there is considerable difference of opinion in the medical profession concerning the methods and efficiency of the treatment of posterior protrusions of the nucleus pulposus from ruptured lumbar intervertebral disks. Underlying this there is an even greater divergence of views about the criteria that must be met before diagnosing this condition.

In a recent group of papers, Magnuson¹ points out that a fine differential diagnosis is necessary in low-back cases and that the recent neurosurgical approach to this diagnostic problem, which has been made "mainly from this standpoint of root pressure from a ruptured intervertebral disk, . . . , seems much too narrow." He points out that variations in the size of the intervertebral foramina and local joint disease cause the low-back pain and associated sciatica that is generally ascribed to disk herniations. He also makes the important statement that it is always possible through an incision in the annulus to curette or otherwise bring out the material that forms the disk, and he is much opposed to incising the intact annulus as part of an exploration for a suspected disk. Larmon² offers substantiating evidence from anatomic dissection. Caldwell³ discusses spondylolisthesis and spondylolysis as frequent causes of low-back pain, either alone or associated with sciatica, and holds that a compressed root is usually the cause of such symptoms and that it is the decompression of the involved root that is the significant therapeutic procedure. Dandy⁴ has evolved a so-called "concealed disk" that he claims may afflict all the lumbar intervertebral spaces. He appears to believe that the diagnosis of herniation of a lumbar disk presents no problems. In patients with this disease he states that the history is almost pathognomonic, that the localization is perfectly simple and certain, that diagnostic intraspinal injections are not only

unnecessary but ineffective in over two thirds of the cases and that lumbar puncture is needful only if the presence of a tumor of the spinal cord is suspected. It appears, however, that such disks are so well concealed that they can be demonstrated only during operation, and that the indications for surgical interference are the broad ones of an operable patient with a sore back and pain in the leg. Keegan⁵ contends that single nerve roots compressed by herniated disks cause dermatome hypalgesia that is accurately diagnostic of the location and level of the lesion. He states that a conservative attitude should be taken in their treatment because in many early cases improvement occurs without intervention. French and Payne⁶ report 8 cases — to which I can add 1 of rupture of the third lumbar disk, included in the series reported below — of tumorlike compression of the cauda equina by a herniated disk. All his cases as well as the one from my clinic had a complete or virtually complete dynamic subarachnoid block with a high cerebrospinal-fluid protein level and symptoms of cauda equina, rather than of single root, involvement. There was a long history in every case (five years in mine), and there was every reason to suppose that the surgery that was eventually made available would have been more successful had the diagnosis been made and treatment instituted much earlier in the course of the disease. Oppenheimer,⁷ on the basis of roentgenologic experience and a study of the literature, has evolved the term "discogenic disease" to cover a wide variety of signs and symptoms, including pain at all levels of the spine and associated with recurrent attacks of pain in the arm and leg. He makes the statement that disk lesions are about twice as frequent as duodenal ulcer. In contrast to this, Breck, Hillsman and Basom⁸ found that 15 per cent of applicants for heavy work at the plant in Texas where the survey was made had to be rejected because of disease of the lumbosacral spine. This was demonstrated in 450 consecutive pre-employment roentgenograms made in patients without backache either at the time they were seen

COMMENT

Diphtheria continues at a relatively high level — approximately at one and a half times the seven-year median. This indicates, of course, that local immunization effort should be stepped up.

Mumps continues its gradual climb toward higher levels, and scarlet fever is again on the increase after a few months of lower prevalence. Measles and lobar pneumonia, on the other hand, have dropped to almost record low levels.

Malaria is now regularly appearing in the reports of certain boards of health, but this is due to the presence in Massachusetts of service men and others who have acquired the disease in foreign service.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Arlington, 1; Boston, 3; Hadley, 1; Holyoke, 1; Newton, 1; Oxford, 1; Waltham, 1; Wellesley, 1; West Springfield, 1; total, 11.

Diphtheria was reported from: Barnstable, 4; Boston, 6; Bourne, 1; Falmouth, 1; Lowell, 1; Medford, 1; New Bedford, 4; Rockland, 1; Salem, 1; Somerville, 7; Wakefield, 1; Weymouth, 1; total, 29.

Dysentery, bacillary, was reported from: Amherst, 2; Everett, 1; Lowell, 1; Malden, 4; Medford, 2; Northampton, 1; Quincy, 1; total, 12.

Encephalitis, infectious, was reported from: Medford, 1; Winchendon, 1; total, 2.

Malaria was reported from: Amesbury, 1; Camp Edwards, 9; Cushing General Hospital, 3; Dedham, 1; Easton, 1; Everett, 1; Hardwick, 1; Haverhill, 2; Ipswich, 1; Marlboro, 1; Newton, 2; Quincy, 1; Regional Hospital, Waltham, 16; Somerville, 1; Stoneham, 1; total, 42.

Meningitis, meningococcal, was reported from: Arlington, 1; Attleboro, 1; Boston, 8; Bridgewater, 1; Fall River, 2; Framingham, 1; Gloucester, 1; Haverhill, 1; Lawrence, 1; Lynn, 1; Malden, 1; Medford, 1; Melrose, 1; Newton, 1; Saugus, 1; Somerville, 1; Weymouth, 1; Worcester, 1; total, 26.

Meningitis, Pfeiffer-bacillus, was reported from: Arlington, 1; Boston, 2; Cambridge, 1; Hanson, 1; Medford, 1; Watertown, 1; total, 7.

Meningitis, pneumococcal, was reported from: Boston, 1; Brockton, 1; Chicopee, 1; Lawrence, 1; Lynn, 1; Marion, 1; Medford, 1; Springfield, 1; Westport, 1; total, 9.

Meningitis, other forms, was reported from: Boston, 1; total, 1.

Meningitis, undetermined, was reported from: Boston, 1; total, 1.

Salmonella infections were reported from: Lawrence, 2; North Andover, 1; Somerville, 1; Southbridge, 1; total, 5.

Septic sore throat was reported from: Avon, 2; Belmont, 1; Boston, 14; Marion, 1; Medford, 1; Merrimac, 1; Revere, 1; total, 21.

Tetanus was reported from: Medway, 1; total, 1.

Trachoma was reported from: Lee, 1; Watertown, 1; total, 2.

Trichinosis was reported from: Boston, 4; total, 4.

Typhoid fever was reported from: Boston, 2; Haverhill, 1; Lawrence, 1; Tewksbury, 1; Warren, 1; total, 6.

Typhus fever was reported from: Boston, 1; total, 1.

Undulant fever was reported from: Boston, 1; Bourne, 1; Sheffield, 1; total, 3.

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

Friday, February 2 — Medical Disorders in Pregnancy. Dr. Lewis Dexter.
Tuesday, February 6 — Neuro-Hormonal Factors in the Origin and Treatment of Cardiovascular Disease. Dr. W. Raab.
Wednesday, February 7 — My Recent Trip to the West Indies. Dr. William Dameshek.
Friday, February 9 — Erythrocyte Preservation. Dr. Joseph F. Ross.
Wednesday, February 14 — Bronchiectasis: Medical and surgical aspects. Dr. Bert Cotton.
Friday, February 16 — Dwarfism. Dr. Nathan Talbot.
Wednesday, February 21 — Interesting Effects on Lungs and Air Passages of Breathing Extremely Hot or Cold Air. Dr. Alan R. Moritz.
Friday, February 23 — Protein Nutrition in Problems of Medical Interest. Dr. Fredrick J. Stare.
Wednesday, February 28 — Penicillin in Venereal Disease. Dr. Oscar F. Cox.

On Monday mornings clinics will be given by Dr. Samuel Proger. On Saturday mornings clinics will be given by Dr. William Dameshek. On Tuesday and Thursday mornings Dr. S. J. Thannhauser will give medical clinics on hospital cases.

MASSACHUSETTS PHYSIOTHERAPY ASSOCIATION

The next meeting of the Massachusetts Physiotherapy Association will be held at the Women's Educational and Industrial Union on Tuesday, February 6. At 7:00 p.m., following a dinner and business meeting, Miss Margaret Arey, supervising instructor in public-health nursing in orthopedics in Massachusetts, will talk on the subject "The Care of Patients with Amputations."

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of the Peter Bent Brigham Hospital on Tuesday, February 13, at 8:15 p.m.

PROGRAM

Clinical case presentation from the Boston City Hospital.
The Distribution of Lipids in Blood Cells and Plasma.
Drs. F. F. Foldes and A. J. Murphy.
Histochemical Studies of the Retina. Dr. C. B. Anfinsen.
Studies on Recently Isolated Influenza Viruses. Drs. J. F. Enders, M. Finland, E. G. Mills and M. W. Barnes.

(Notices continued on page xix)

ANALYSIS OF RESULTS

Age and Sex Incidence

Table 1 shows the age and sex distribution in each series. The latter was about the same in both series. Furthermore, 85 per cent of the proved herniation cases occurred between the ages of twenty and fifty, compared with 83 per cent for similar conditions. Thus, it cannot be said from my experience that the age and sex of a patient

lifting strain, a back injury or a fall weights the diagnostic scales in favor of a herniation as against similar conditions. A complete absence of a history of injury neither favors nor militates against a diagnosis of herniation. The relation to injury in industry is of no diagnostic significance.

Time Relations

In Table 3 are analyzed the intervals elapsing between the first attack of pain and hospitalization

TABLE 1. Sex and Age Incidence.

-SERIES	SEX		AGE							LOWEST	HIGHEST
	M	F	1-10 yr.	10-20 yr	20-30 yr	30-40 yr	40-50 yr	50-60 yr.	60-70 yr.	yr.	yr.
Proved herniations	55	20	0	2	11	29	26	7	5	17	67
Similar conditions	51	10	0	0	5	13	16	7	1	26	66

with pain in the back or leg is of any aid in the differential diagnosis of a herniated lumbar disk.

Etiology

Table 2 shows the comparative figures for the type of injury, including the number and percentage of injuries received in industry. Certain of these findings should be emphasized. For example, it was as usual for a herniation of a lumbar disk to develop in the absence of any history of injury as it was for it not to do so. This agrees with the findings of Bradford and Spurling.¹⁰ Love,¹¹ how-

and those between the start of the attack that led the patient to seek relief at the Boston City Hospital. These figures are neither helpful nor significant from the point of view of differential diagnosis. They do demonstrate, however, the extraordinary length of time that a patient is willing to suffer before seeking or consenting to hospitalization.

Symptoms and Signs

The foregoing are more or less routine considerations in the analysis of any such series. The analysis of subjective symptoms and objective signs (Tables

TABLE 2. Etiology.

ever, states that there is usually a history of trauma or unusual stress or strain to the back. Lifting strain was twice as frequent a cause of herniation as of similar conditions, back injuries were three times as frequent, and falls were one and a half times as frequent. The incidence of industrial cases for each type of injury was approximately the same in both series except that all the cases with similar conditions caused by lifting strain were industrial whereas only three quarters of the cases with herniation from the same cause were industrial. There were no postoperative cases in the proved series, and there was no significant difference in industrial distribution between the two series as a whole. Other things being equal, a history of a

4 and 5) is of more interest and significance. The subjective symptoms of pain have been analyzed in some detail because pain is unquestionably the most significant symptom of herniated lumbar disks. The first attack of pain occurred most frequently in the back, where a disk had herniated or was about to herniate or where some similar condition was present or was about to develop (Table 4). The difference in frequency is not great and is probably not significant diagnostically, the frequency being only 10 per cent higher in the proved disk cases than in the other conditions. The number of cases in which pain was absent in the back at the first attack but occurred instead in the leg or legs, including the hip and thighs, should be noted. The

or previously. Finally, Shinnors and Hamby⁹ make the statement that claim adjusters of at least one insurance company are known to discourage compensation patients disabled by protruded intervertebral disks from seeking surgical relief, and there is certainly a well-founded but undocumented belief that other insurance companies, members of industrial accident boards and of the medical departments of the Army and Navy and many members of the civilian medical profession regard the diagnosis of herniation of a lumbar intervertebral disk with considerable skepticism until the weight of evidence in its favor is overwhelming.

My experience has led me to believe that the clinical diagnosis of a posterior herniation of the nucleus pulposus of a ruptured lumbar intervertebral disk that is based only on the history and physical and neurologic examinations, if unconfirmed by other objective findings, is at best only a "possible" one. Such a low level of accuracy is certainly not ideal. Moreover, even if greater accuracy were possible and the means used to obtain it were safe, it would still not be in the best interests of the patient to advise operative interference on this basis in the usual case and in the absence of an emergency, nor could one expect the patient to accept such advice without demur. Indeed we should scarcely be willing to do so ourselves. The continued search for a substance that visualizes these lesions with a reasonable degree of accuracy and that is simple and safe, as well as the continued use of admittedly unsatisfactory mediums designed for this purpose, emphasizes the general recognition by the medical profession of the need for improvement in diagnostic accuracy and their distrust of unconfirmed clinical criteria. It is the primary purpose of this paper to present evidence to support this contention. Secondly, I wish to make a brief preliminary report on a new substance to be used for visualization of the lumbar subarachnoid space that so far has met all the requirements noted above. This substance is 20 per cent Skiodan.

So far as I am aware, the best statement of the requirements that must be met before a clinical diagnosis of posterior herniation of the lumbar disks can be made is that published by Bradford and Spurling.¹⁰ More recently Love¹¹ has also listed essentially the same requirements. They comprise a history of trauma or of unusual strain to the back, with subsequent intractable backache or sciatic pain, or both. The back pain usually precedes the leg pain. The pain is said to be intermittent and not relieved by the ordinary therapeutic procedures. On examination the spinal muscles are spastic, spinal motion is limited and painful, and the straight-leg-raising test is positive. Neurologic signs are often minimal. They include absence or diminution of one Achilles reflex and variable areas of altered sensation in the affected extremity. Bradford and Spurling state that the latter occurs in

75 per cent of the cases examined and that numbness and paresthesias in the lateral aspect of the leg and foot are frequent. They also differentiate¹ a herniation of the fourth and the lumbosacral disk by the distribution of the sensory loss, especially with reference to the great and other toes, and by changes in the ankle jerk. They lay great stress on the jugular-compression test and the effects on the pain of coughing, sneezing or straining, as well as the diagnostic conclusions that may be drawn from these findings. It is generally recognized that herniations may occur at any level of the lumbar spine and may be multiple. Bradford and Spurling, as well as Love, advocate the use of contrast mediums as an aid to diagnosis, but the former writes, "There has been unwarranted emphasis on the difficulty of recognizing clinically cases of herniated nucleus pulposus," and the latter states, "In the majority of cases . . . the diagnosis can be accurately made on the basis of the history and physical findings."

MATERIAL

In an attempt to verify these statements, I have analyzed two parallel series of cases in which the history and physical findings might be generally considered to justify a diagnosis of herniation of a lumbar disk. In one series of 78 cases a herniation was proved to have been present by operation and by pathological examination of the removed material in all but 3 cases, which had unmistakable and characteristic myelogram deformities. The comparable series was made up of 41 cases with the following diagnoses: suspected ruptured intervertebral disk, 13 cases (proved negative by operation in 10); compressed root from a small dural envelop or local scar or resulting from a fractured lumbar vertebra, 19 cases (in 14 of which the diagnosis was verified by operation); questionable radiculitis, the cause of which was not apparent, 4 cases (verified by operation in all); a congenital defect without other demonstrable disease, 2 cases (verified by operation in both); and back strain, 3 cases (verified by operation in 1). Of 9 cases listed above as not having been verified by operation, an abdominal aortic aneurysm was visible by x-ray in 1. There was a negative myelogram in this case. In 1 case there were four negative myelograms; operation was not performed in spite of a so-called "typical history." In 1 there was an unquestionably positive myelogram and operation was offered but refused. Five patients had had herniated disks previously removed elsewhere, only to have the symptoms recur in from four to eleven months thereafter. In 2 of these cases the myelogram was positive (abnormal but not characteristic of herniation), and in 1 it was negative. All 5 patients are awaiting re-operation. The last patient had a suggestive clinical history and examination and a questionable myelogram and has refused operation.

ANALYSIS OF RESULTS

Age and Sex Incidence

Table 1 shows the age and sex distribution in each series. The latter was about the same in both series. Furthermore, 85 per cent of the proved herniation cases occurred between the ages of twenty and fifty, compared with 83 per cent for similar conditions. Thus, it cannot be said from my experience that the age and sex of a patient

lifting strain, a back injury or a fall weights the diagnostic scales in favor of a herniation as against similar conditions. A complete absence of a history of injury neither favors nor militates against a diagnosis of herniation. The relation to injury in industry is of no diagnostic significance.

Time Relations

In Table 3 are analyzed the intervals elapsing between the first attack of pain and hospitalization

TABLE 1. Sex and Age Incidence.

with pain in the back or leg is of any aid in the differential diagnosis of a herniated lumbar disk.

Etiology

Table 2 shows the comparative figures for the type of injury, including the number and percentage of injuries received in industry. Certain of these findings should be emphasized. For example, it was as usual for a herniation of a lumbar disk to develop in the absence of any history of injury as it was for it not to do so. This agrees with the findings of Bradford and Spurling.¹⁰ Love,¹¹ how-

and those between the start of the attack that led the patient to seek relief at the Boston City Hospital. These figures are neither helpful nor significant from the point of view of differential diagnosis. They do demonstrate, however, the extraordinary length of time that a patient is willing to suffer before seeking or consenting to hospitalization.

Symptoms and Signs

The foregoing are more or less routine considerations in the analysis of any such series. The analysis of subjective symptoms and objective signs (Tables

ever, states that there is usually a history of trauma or unusual stress or strain to the back. Lifting strain was twice as frequent a cause of herniation as of similar conditions, back injuries were three times as frequent, and falls were one and a half times as frequent. The incidence of industrial cases for each type of injury was approximately the same in both series except that all the cases with similar conditions caused by lifting strain were industrial whereas only three quarters of the cases with herniation from the same cause were industrial. There were no postoperative cases in the proved series, and there was no significant difference in industrial distribution between the two series as a whole. Other things being equal, a history of a

4 and 5) is of more interest and significance. The subjective symptoms of pain have been analyzed in some detail because pain is unquestionably the most significant symptom of herniated lumbar disks. The first attack of pain occurred most frequently in the back, where a disk had herniated or was about to herniate or where some similar condition was present or was about to develop (Table 4). The difference in frequency is not great and is probably not significant diagnostically, the frequency being only 10 per cent higher in the proved disk cases than in the other conditions. The number of cases in which pain was absent in the back at the first attack but occurred instead in the leg or legs, including the hip and thighs, should be noted. The

patient's description of the location of the pain during the course of the disease pointed to the leg, exclusive of the foot, as the preponderant location, and to the lower leg as the most frequent site. This

33 per cent in the other series. Pain was increased by coughing, sneezing or straining in 63 per cent of the proved herniation series, as against 40 per cent in the other series, and exercise was more

applies to both series. The infrequency with which the foot and especially the toes are involved is in disagreement with the usual description of the symptoms of herniated lumbar disk. There is

frequently mentioned in the nonherniated series a causing increased pain. As would be expected, rest and orthopedic treatment were the most effective means of decreasing the pain in both series. From

nothing in these figures that is otherwise of aid in the differential diagnosis of herniation. The pain when present was most frequently described as a constant severe ache and was often associated with subjective numbness. Intermittent pain during the attack was only about one third as frequent as the constant type in both series (Table 5). In 64 per cent of the proved herniations there was a history of recurrent attacks of pain, as compared with

these data it seems reasonable to conclude that a history of recurrent attacks of pain in the lower back and leg, which occur first as pain in the low back and are increased by coughing, sneezing or straining and relieved by rest or orthopedic treatment, is somewhat more indicative of a herniation of a lumbar disk than it is of any similar condition. Subjective symptoms as described by the patient appear to be of no value in identifying the level at

which the disk is ruptured, provided such a rupture is present.

The results of certain objective tests are listed in Table 6. No claim is made that they are com-

come for diagnosis to the general surgeon and not to the specialist. The demonstration of borderline sensory changes, for example, may depend quite as much on the examiner as on the patient, and an

to be significant. Attempts to be too meticulous and to ascribe too great a significance to variations that arise primarily out of the examiner's desire to bolster a preconceived diagnosis may be a source of error. This is not without importance, because there is no doubt that the majority of these patients first

orthopedic surgeon will measure the amount of straight-leg raising in degrees, the more usual interpretation is covered by the terms "present" and "absent." This more liberal and possibly less exact method of listing the results of these tests is more suited to the present knowledge of the condi-

patient's description of the location of the pain during the course of the disease pointed to the leg, exclusive of the foot, as the preponderant location, and to the lower leg as the most frequent site. This

nothing in these figures that is otherwise of aid in the differential diagnosis of herniation. The pain when present was most frequently described as a constant severe ache and was often associated with subjective numbness. Intermittent pain during the attack was only about one third as frequent as the constant type in both series (Table 5). In 64 per cent of the proved herniations there was a history of recurrent attacks of pain, as compared with

these data it seems reasonable to conclude that a history of recurrent attacks of pain in the lower back and leg, which occur first as pain in the low back and are increased by coughing, sneezing or straining and relieved by rest or orthopedic treatment, is somewhat more indicative of a herniation of a lumbar disk than it is of any similar condition. Subjective symptoms as described by the patient appear to be of no value in identifying the level at

significance, positive tests being considered by many physicians as practically pathognomonic of rupture of a disk. The figures shown here do not bear this out (Table 6). Whereas 85 per cent of the patients with herniations had a positive straight-leg-raising reaction, 71 per cent of the other series had the same sign. Even if the percentages are figured on the basis of either or both tests' being positive, the comparative figures are still 86 and 70 per cent.

conditions. The numbers are too small to permit any conclusions to be drawn in regard to the jugular-compression test, but there is no doubt that it, too, would show similar results. Neither test helps to differentiate a herniation from a tumor of this region. In this instance my figures are in accord with the statements made by Bradford and Spurling.

Objective motor signs. Weakness of the legs occurred in 32 per cent of the cases in each series,

FIGURE 2. Residual Lipiodol, Injected Elsewhere, before (left) and after (right) Attempts at Removal. This patient had symptoms because of root compression by encysted globules of lipiodol. This was verified by operation.

From my experience it appears that a positive straight-leg-raising or Lasègue test, whether considered separately or together, only indicates some trouble with the lumbosacral roots or the cauda equina. This trouble may vary from a congenital defect of the spine through a postoperative scar compression of one or more nerve roots to a posterior herniation of a lumbar disk. Doubtless other conditions could be included.

Tests producing temporary increase of intracranial pressure. The only significant figures in this regard are those of the cough test (Table 6). Just as in the history, this test is of considerable differential diagnostic import. Although it was positive in 86 per cent of the proved herniation series, there was a similar finding in only 44 per cent of the similar

whereas paralysis was present so infrequently as to be of no significance (Table 6). There was complete absence of both weakness and paralysis in the same percentage of each group. Atrophy was about three times as frequent in the proved herniation series as in the other series, and a Babinski toe response was present in only 2 cases of the second series. If leg atrophy is present in a patient suspected of having a herniated lumbar disk, the chances based on this finding only are three to one in favor of this diagnosis.

Tendon reflexes. Great diagnostic and localizing importance has been attached to the absence of an ankle jerk as a sign of herniation of a lumbar disk. My figures show that in patients with proved herniation it is slightly more usual to find the ankle jerks

tion in question. Attempts to be more accurate are analogous to figuring percentages in groups of two-digit numbers to six decimal places; the one is no more diagnostically significant than the other is mathematically so. It is for this reason that in this study the sciatic-nerve stretch tests, the objective sensory changes and other signs, the reflex response and similar reactions are noted only as being present or absent or normal or abnormal.

importance in differentiating a herniation from similar conditions. The figures in the present series support these contentions feebly if at all (Table 6). In particular it should be noted that exclusive of local tenderness no back signs were demonstrable in one fifth of the proved herniations and in one third of the similar conditions. Local tenderness was present in half of the latter as opposed to slightly less than two thirds of the former. As differentially

lateral to the spinous processes is, according to Bradford and Spurling,¹⁰ of particular diagnostic

tests, particularly the former. are generally considered to have a considerable differential diagnostic

fourth or the lumbosacral disk that had been ruptured. The number of patients with sensory loss in the great or other toes also seems significant from this point of view. Of the 7 patients with involvement of the great toe, 4 showed rupture of the fourth disk and 3 rupture of the lumbosacral disk. Of the patients with involvement of the other toes, 2 had a rupture of the fourth disk, 4 had a rupture of the fifth disk, and 1 had a rupture of the third disk. Loss of the ankle jerk was present in half of the lumbosacral ruptures but in only one third of the fourth-disk ruptures. Weakness was present

contradictory, however, when used to differentiate ruptures of the fourth and fifth disks. If the objective sensory changes are in the lower leg or foot, this also increases the chances of a herniation. Absence of any objective sensory changes does not militate against this diagnosis. Spasm of the back muscles, abnormal postures, changes in the lumbar curve, loss or diminution of back motion, local tenderness anywhere in the lumbosacral area and a positive straight-leg-raising or Lasègue test are no more characteristic or diagnostic of a posterior herniation of a lumbar disk than they are of any

FIGURE 4. *The Normal Lumbosacral Subarachnoid Space Outlined by Skiodan. The droplets are from a previous Lipiodol injection done elsewhere and remaining after removal of the bulk of the oil.*

to an equal degree at both levels, but atrophy was twice as frequent with rupture of the higher of these disks. There was no significant difference between the levels in the rate of occurrence of either the positive Lasègue or the positive straight-leg-raising test. On the basis of this series the only objective test with any significant localizing value regarding the level of rupture is absence of the ankle jerk on the affected leg. The presence of atrophy may be of some localizing value.

It seems only reasonable to conclude from these figures that a patient who has an onset of sciatic pain or who has that pain increased if it is already present, by any test that increases the intracranial pressure has a slightly better than two to one chance of having a herniated disk as the cause of his pain if he has no intraspinal tumor. If he has an absent ankle jerk and atrophy of some of the muscles of the affected leg, his chance of having a herniation is slightly increased. These two tests are mutually

other of a variety of low-back, lumbosacral-root or cauda-equina diseases or injuries.

Cerebrospinal-fluid data. As has been repeatedly emphasized, alterations in the pressure, dynamics and total protein content of the cerebrospinal fluid below the level of a herniated lumbar disk are no more characteristic of this condition than they are of any other condition that interferes with the circulation of the fluid. Love¹¹ differentiates herniations and tumors on the basis of total protein content, claiming that values over 100 mg. per 100 cc. usually mean a neoplasm. The present series of conditions similar to herniated disk contained only 1 patient with a tumor. This tumor did not cause a block and the protein content was below 50 mg. It is impossible to draw any conclusions about this particular differential diagnostic problem. I am in complete agreement with Love, however, on the basis of other experience that in "unexplained intractable root pain and in almost every

normal than it is to find them absent in either leg (Table 6). Reference to Table 7 demonstrates that in the proved herniation series its presence and absence were of equally little value in helping to determine which if any disk was ruptured. There was an occasional absent knee jerk in both series, but the figures are too few to justify any conclusions.

Objective sensory changes. Just as with the subjective sensory symptoms, the most frequent site for objective sensory changes in proved herniations was in the lower leg, with the foot second (Table 6). This holds true also for the other series, although the preponderance is not so great. The absence of

herniations and in 47 per cent of the similar conditions there was no demonstrable sensory loss of any type in the lower extremities. This does not agree with Bradford and Spurling's¹⁰ statement that 75 per cent of patients with herniations have a demonstrable hypesthesia, but is more nearly in accord with Love's¹¹ experience that neurologic signs are usually minimal, with hypesthesia or anesthesia over a small segment of the surface of the skin. The importance of objective sensory changes is considerably diminished in the light of these figures, whether considered from the point of view of differential diagnosis or from that of localization

FIGURE 3. Positive Two-Needle Lateral and Anteroposterior Oxygen Myelograms.

positive findings in the toes and particularly in the great toe is especially remarkable. The contrary has been emphasized many times as an important

Level of herniation. In Table 7 are listed certain of the above tests with reference to the particular disk that has been ruptured. Mention has already

TABLE 8. Data on Cerebrospinal Fluids and Myelograms.

differential diagnostic finding, but such a conclusion is not justified by these figures. Most important of all is the fact that in 37 per cent of the proved

been made of the high percentage of patients who showed no loss of sensation. This finding occurred at approximately the same rate whether it was the

needle technic as a contrast medium (Table 8). Until the present manpower shortage affected the supply of skilled x-ray technicians and dark-room workers a fairly satisfactory level of accuracy could be maintained. This was never considered an ideal medium, however, and in the last two years or more it has hardly met minimal requirements. As will be seen from Table 8 about 30 per cent of the examinations were either wrong or not usable for diagnostic purposes. About one and a half years ago, my then resident, Dr. Philip R. Vogel, suggested the use of Skiodan intrathecally as a contrast medium. Before leaving for service in the Army he had completed sufficient preliminary work to demonstrate that a 20 per cent solution of Skiodan could be used in this way with safety and with an

publication. On the evidence collected so far it appears to me and my co-workers that a 20 per cent solution of Skiodan satisfies all the requirements postulated above as necessary to justify the routine use of a contrast medium in the diagnosis of posterior herniation of the lumbar disks. Even were this not so, however, such diagnoses can usually be made with the aid of one of the less satisfactory mediums, and a diagnosis without that aid does not give the patient the full benefit of the surgeon's knowledge and diagnostic opportunities.

CONCLUSIONS

A clinical history and examination that even include a study of the cerebrospinal fluid are not enough to justify an indisputable diagnosis of pos-

FIGURE 6. Positive Skiodan Myelograms.

A and B are anteroposterior and lateral views showing a typical deformity at the level of the fifth lumbar intervertebral disk. C and D are anteroposterior and lateral views of the same patient eight months after removal of the disk. There was a compression radiculitis caused by postoperative scarring, with recurrence of the original symptoms; this was verified by operation.

inconsequential amount of meningeal irritation. provided spinal analgesia — not anesthesia — was first produced (Fig. 4). The injected material was completely absorbed in two hours, and the contrast obtained was as good as or better than that obtained by lipiodol. The use of a fluoroscope was not necessary. Since the technic required making the test with the patient's head elevated, it was thought that the chance of demonstrating borderline herniations was better than with any other method. Individual fibers of the cauda were outlined and the subarachnoid root sleeves were constantly visualized around every root (Fig. 5). Lateral views were equally satisfactory (Fig. 6). The clinical work was then stopped until animal experimentation could verify the safety of the material. This has now been done and recently further more exact and more detailed clinical tests have been carried out as well. An extended report of this work, including a description of the method, will shortly be submitted for

publication. On the evidence collected so far it appears to me and my co-workers that a 20 per cent solution of Skiodan satisfies all the requirements postulated above as necessary to justify the routine use of a contrast medium in the diagnosis of posterior herniation of the lumbar disks. Even were this not so, however, such diagnoses can usually be made with the aid of one of the less satisfactory mediums, and a diagnosis without that aid does not give the patient the full benefit of the surgeon's knowledge and diagnostic opportunities.

terior herniation of a lumbar disk. An unequivocal recommendation of surgery as a method of treatment is equally unjustifiable under such circumstances. If, however, one can demonstrate a sensory deficit that corresponds to the peripheral distribution of a low lumbar or upper sacral root, together with atrophy and loss of ankle jerk in the same leg, a diagnosis of irritation or compression of this particular root is justified. If in addition there is a history of intermittent attacks of pain in the back with radiation to any part of the leg, especially to the lower leg, which is associated with initiation or increase of the typical pain by coughing, sneezing or straining, or by back motion or lifting, and if these attacks started after a back injury, back strain, lifting strain or fall, a posterior herniation of either the fourth lumbar or lumbosacral disk must be seriously considered as a cause of the radiculitis. This cannot be regarded as anything approaching a certainty, however, unless

case in which protruded intervertebral disk is suspected diagnostic lumbar puncture should be performed." Insofar as my figures go, the cerebrospinal-fluid pressure, dynamics and total protein (Table 8) were of no help in making a differential diagnosis of posterior herniation of a lumbar disk.

Myelography. Almost everyone concerned with the problem of diagnosing and treating posterior herniations of the lumbar disk admits that visualization of the lumbar and sacral subarachnoid space

to be removed by a second procedure, which, although done easily by some, is of some magnitude in the hands of most surgeons (Fig. 2). Pantopaque, the use of which has until recently been limited almost entirely to the medical departments of the Army and Navy, is the next best medium, but except that it is much less irritating and does not have to be removed, it has the same disadvantages that lipiodol has. The use of oxygen and air presents considerable technical x-ray difficulty, and the

FIGURE 5. *Positive Lateral and Anteroposterior Skiogram Myelograms that Show Filling of the Subarachnoid Sleeves Around the Roots.*

is a highly desirable diagnostic prerequisite. Most of this group would also agree that it is an essential if it can be done easily, comfortably and safely and if the degree of accuracy approaches perfection. One has only to refer to the long-continued use of admittedly unsatisfactory mediums and the number and persistence of the attempts that have been made to find a satisfactory one to verify this impression. Of the media commonly in use, lipiodol certainly affords the best contrasts (Fig. 1). It is an oily solution, however, and as such may lead to false positives through partial emulsification when mixed with the watery cerebrospinal fluid. Examinations made with it have to be done with the aid of a fluoroscope and by a roentgenologist capable of operating this apparatus. It is irritating and has

percentage of unsatisfactory films and wrong diagnoses is admittedly too high. In addition, the examination must be made with the feet higher than the head, and this position must be maintained for twenty-four hours or longer if post-lumbar puncture headache, which may be extremely severe, is to be even partly avoided. To be sure, a fluoroscope is not required, the gas absorbs itself, and there is little or no meningeal irritation. Two lumbar punctures are required to get the greatest number of satisfactory visualizations (Fig. 3).¹² Thorotrast and iodine in poppyseed oil have also been used, but the former is considered too dangerous and the latter does not provide adequate contrast, so that their use has been abandoned.

For the most part we have used air by a two-

more particularly of the Rolandic area, produced by histamine effect, is the underlying cause."

The idea that aldehydes and peroxides present as impurities in ether may cause convulsions, held by earlier writers, is now known to be untrue.⁹ Further, this contention cannot hold when convulsions develop with the use of agents other than ether.

Many other etiologic factors have been proposed, often without any sound foundation. Excess and deficiency of carbon dioxide have been suggested, as well as conditions vaguely described as irritability of the nervous system, overbreathing, latent tendency to fits, sex susceptibility and others not worth mentioning. Even a neurotoxin produced by streptococci has been suggested.¹⁰ Certain of the above may possibly influence the development of a convulsion, especially the carbon dioxide content of the blood, but there has not been demonstrated a constant cause-and-effect relation in every case.

There are a few factors, however, that seem to be present in many cases, although not all. These, appearing as a definite undercurrent in most discussions of the problem, are youth, the presence of sepsis with fever, and hot, humid external surroundings. Some have claimed that these convulsions are due to heat stroke. According to Payne,¹¹ however, edema and hyperemia of the brain, with nerve-cell degeneration as described in heat stroke, have not been observed in anesthetic convulsions. In view of the possibility that heat is a factor, other writers have suggested that the preoperative administration of atropine is deleterious, the drug acting by inhibiting heat loss. Regarding high wet-bulb temperature, it is interesting to note Brennan's¹² statement to the effect that no convulsion occurred in any of five busy theaters after they had been air conditioned six years previously.

These convulsions can appear at any time, and although several authorities have stressed the importance of neurogenic stimuli,¹² with the convulsion commencing at the moment the peritoneum is grasped in forceps or incised, or as soon as there is traction on the viscera, several cases have commenced after the completion of the surgical procedure and the discontinuance of the anesthetic.

Whereas it is well to be aware of the possibly deleterious factors of youth, heat and sepsis, it must be admitted that the etiology of anesthetic convulsions is quite unknown, that their onset cannot be predicted in any case and that the practical problem is what to do about them.

The mortality rate is 20 to 25 per cent. Death may occur at any time. One of Tye's patients¹³ lived for twenty-nine days in a state of decerebrate rigidity without regaining consciousness. That one can survive a violent convulsion has been shown many times, as is illustrated in the case reported below.

The subject of treatment is also somewhat confused. For example, some have claimed to have effected cessation of the convulsion merely by raising the head, and others by elevating the feet. Whereas most writers state that withdrawal of the anesthetic is imperative, Tye¹³ believes that deeper anesthesia is needed. My opinion in the matter is the same, but I should accomplish this end by discontinuing the inhalation anesthetic and substituting one of the intravenous barbiturates, either 5 cc. or more of a 2.5 per cent solution of Pentothal Sodium, as recommended by Lundy,¹⁴ or 0.5 gm. of sodium amytal. Should these not be immediately available, intravenous magnesium sulfate may be given, since magnesium is not only a depressant of the central nervous system but also blocks the nervous stimulation of voluntary muscles.⁷ In the event of an overdose of magnesium, it is to be remembered that respiratory failure from such a cause is best combated not by the usual respiratory stimulants but by intravenous calcium. Concomitantly intratracheal oxygen should be administered. Of course, the operation should be completed as quickly as possible. For hyperthermia, ice bags placed on the body assist in lowering the temperature. If severe hypertension develops, phlebotomy and drainage of spinal fluid are advisable.

CASE REPORT

R. W., a well-developed and nourished 17-year-old boy, entered the Mercy Hospital on March 18, 1944, complaining of abdominal pain for 24 hours. From the history and physical examination, together with a white-cell count of 22,300 and a rectal temperature of 99.8°F., a diagnosis of acute appendicitis was made. The patient was given 11 mg. of morphine sulfate and 0.4 mg. of atropine sulfate. Forty-five minutes later anesthesia with nitrous oxide, oxygen and ether was started.

Whereas the patient came to the operating room feeling apprehensive, the induction was fairly smooth, and at the beginning of the operation 15 minutes later the patient was well relaxed and showed the ordinary signs of anesthesia, with good color, the pulse, respirations and blood pressure (150/70) being within normal limits. Through a McBurney incision a gangrenous retrocecal appendix was found and freed with some difficulty, during which there was considerable tugging on the cecum. As the appendix was freed, and just prior to removal, the anesthetist noticed twitchings of the neck muscles, and 30 seconds later these became generalized. The convulsion lasted for 35 minutes. As soon as the twitching became generalized and violent, the surgeon who was assisting left the operative field to deal with the emergency, while with the help of the scrub nurse I proceeded with the removal of the appendix and the wound closure, this being accomplished with considerable difficulty, since the patient was making violent convulsive movements.

The pupils were widely dilated during the convulsive seizure. The blood pressure during most of the time was too high to be recorded. The highest systolic record was 280, and the diastolic pressure at that time was 130. During this interval the pulse rose to 160 to 180 and the rectal temperature rapidly rose to 104°F. As soon as the convulsion started oxygen was given under pressure and was continued until the attack ceased. A phlebotomy was performed, 600 cc. of blood being removed, and then 50 cc. of 50 per cent glucose solution and 20 cc. of 10 per cent magnesium sulfate were administered intravenously. As soon as the wound was closed, the patient was rolled on his side and 15 cc. of spinal fluid was removed; it was not under

confirmed by other and more accurate data. Additional symptoms and signs, whether present or absent, neither strengthen nor weaken this possibility. A positive straight-leg-raising or Lasègue test, limitation or loss of back motion, a change in the lumbar curve, spasm of the erector spinae muscles and local tenderness in the lumbosacral area indicate only that the patient has some trouble with his low back, lumbosacral roots or cauda equina and neither confirm nor deny the diagnosis of a herniation.

A history and examination such as given above, if accompanied by a partial or complete dynamic block or an increase in the total protein of a sample of cerebrospinal fluid properly collected from below the level of the block, or both of these, justify a diagnosis of irritation or compression of any part or all the cauda equina and a probable diagnosis of either an intraspinal tumor or a midline posterior herniation of a lumbar disk. Final differentiation must at least await myelography, and in many cases operation.

The level of herniation, if one is present, is usually not determinable on the basis of pure clinical data, and it is entirely out of the question to diagnose and to localize multiple herniations without adequate actual preoperative visualization of the lower subarachnoid space.

Certain diagnosis, both concerning the presence of a herniation or herniations and concerning the

level, depends on adequate visualization of the lumbosacral subarachnoid space by some opaque contrast medium. So far, a 20 per cent solution of Skiodan has proved satisfactory for this purpose.

Clinical examinations lay the groundwork for suspecting the presence of a posterior herniation of a lumbar disk. Contrast myelography proves or disproves this suspicion, determines the level of the herniation, and leads to a minimal amount of surgery, should this be indicated.

CONVULSIONS DURING GENERAL ANESTHESIA

EDMUND E. SIMPSON, M.D.

SACRAMENTO, CALIFORNIA

THE development of a convulsion in a patient while under general anesthesia is indeed a harrowing experience. Approximately 200 cases have been reported since 1927, but before that time, for some unexplained reason, there appears to have been little on the subject in the literature. Apparently the earliest report is that of Patch.¹ Later, Taylor² recounted a case of convulsions under ether anesthesia occurring in the late eighteen-forties. It was not until 1927, however, that general interest became manifested in the condition following publication of the papers of Pinson,³ who attributed the attacks to excessive concentrations of carbon dioxide, and of Wilson,⁴ who believed that impurities in the ether were responsible.

The older term "ether convulsions" is inappropriate since these attacks have been described as occurring as well under anesthesia employing nitrous oxide and oxygen, chloroform, vinethene, ethylene and cyclopropane. The attack itself almost

uniformly commences with twitchings about the eyelids or face or neck muscles and rapidly spreads to the entire body, with generalized and violent clonic convulsive movements. There have been no reports of one development under these circumstances, namely, that of extreme hypertension, to be described below.

A great deal has been written in an attempt to explain the cause of this phenomenon. Lund⁵ listed thirty-three possible causes mentioned in the literature, none of these being entirely satisfactory. In fact, there is nothing but contradiction throughout the literature on the etiology of this condition. One of its curious features, as pointed out by Durans,⁶ is that whereas a few authors have described a series of several cases, many surgeons and anesthesiologists have never seen a single case.

Many consider anoxemia to be the cause, but Goodman and Gilman⁷ deny this, stating that the attack may occur in the presence of a high oxygen tension in the blood. Newman⁸ cites an author who stated, "Increased vascularity of the cortex cerebri

*Member of staff, Mercy Hospital, Sacramento, California.

more particularly of the Rolandic area, produced by histamine effect, is the underlying cause."

The idea that aldehydes and peroxides present as impurities in ether may cause convulsions, held by earlier writers, is now known to be untrue.⁹ Further, this contention cannot hold when convulsions develop with the use of agents other than ether.

Many other etiologic factors have been proposed, often without any sound foundation. Excess and deficiency of carbon dioxide have been suggested, as well as conditions vaguely described as irritability of the nervous system, overbreathing, latent tendency to fits, sex susceptibility and others not worth mentioning. Even a neurotoxin produced by streptococci has been suggested.¹⁰ Certain of the above may possibly influence the development of a convulsion, especially the carbon dioxide content of the blood, but there has not been demonstrated a constant cause-and-effect relation in every case.

There are a few factors, however, that seem to be present in many cases, although not all. These, appearing as a definite undercurrent in most discussions of the problem, are youth, the presence of sepsis with fever, and hot, humid external surroundings. Some have claimed that these convulsions are due to heat stroke. According to Payne,¹¹ however, edema and hyperemia of the brain, with nerve-cell degeneration as described in heat stroke, have not been observed in anesthetic convulsions. In view of the possibility that heat is a factor, other writers have suggested that the preoperative administration of atropine is deleterious, the drug acting by inhibiting heat loss. Regarding high wet-bulb temperature, it is interesting to note Brennan's¹² statement to the effect that no convulsion occurred in any of five busy theaters after they had been air conditioned six years previously.

These convulsions can appear at any time, and although several authorities have stressed the importance of neurogenic stimuli,¹² with the convulsion commencing at the moment the peritoneum is grasped in forceps or incised, or as soon as there is traction on the viscera, several cases have commenced after the completion of the surgical procedure and the discontinuance of the anesthetic.

Whereas it is well to be aware of the possibly deleterious factors of youth, heat and sepsis, it must be admitted that the etiology of anesthetic convulsions is quite unknown, that their onset cannot be predicted in any case and that the practical problem is what to do about them.

The mortality rate is 20 to 25 per cent. Death may occur at any time. One of Tye's patients¹³ lived for twenty-nine days in a state of decerebrate rigidity without regaining consciousness. That one can survive a violent convulsion has been shown many times, as is illustrated in the case reported below.

The subject of treatment is also somewhat confused. For example, some have claimed to have effected cessation of the convulsion merely by raising the head, and others by elevating the feet. Whereas most writers state that withdrawal of the anesthetic is imperative, Tye¹³ believes that deeper anesthesia is needed. My opinion in the matter is the same, but I should accomplish this end by discontinuing the inhalation anesthetic and substituting one of the intravenous barbiturates, either 5 cc. or more of a 2.5 per cent solution of Pentothal Sodium, as recommended by Lundy,¹⁴ or 0.5 gm. of sodium amytal. Should these not be immediately available, intravenous magnesium sulfate may be given, since magnesium is not only a depressant of the central nervous system but also blocks the nervous stimulation of voluntary muscles.⁷ In the event of an overdose of magnesium, it is to be remembered that respiratory failure from such a cause is best combated not by the usual respiratory stimulants but by intravenous calcium. Concomitantly intratracheal oxygen should be administered. Of course, the operation should be completed as quickly as possible. For hyperthermia, ice bags placed on the body assist in lowering the temperature. If severe hypertension develops, phlebotomy and drainage of spinal fluid are advisable.

CASE REPORT

R. W., a well-developed and nourished 17-year-old boy, entered the Mercy Hospital on March 18, 1944, complaining of abdominal pain for 24 hours. From the history and physical examination, together with a white-cell count of 22,500 and a rectal temperature of 99.8°F., a diagnosis of acute appendicitis was made. The patient was given 11 mg. of morphine sulfate and 0.4 mg. of atropine sulfate. Forty-five minutes later anesthesia with nitrous oxide, oxygen and ether was started.

Whereas the patient came to the operating room feeling apprehensive, the induction was fairly smooth, and at the beginning of the operation 15 minutes later the patient was well relaxed and showed the ordinary signs of anesthesia, with good color, the pulse, respirations and blood pressure (150/70) being within normal limits. Through a McBurney incision a gangrenous retrocecal appendix was found and freed with some difficulty, during which there was considerable tugging on the cecum. As the appendix was freed, and just prior to removal, the anesthetist noticed twitchings of the neck muscles, and 30 seconds later these became generalized. The convulsion lasted for 55 minutes. As soon as the twitching became generalized and violent, the surgeon who was assisting left the operative field to deal with the emergency, while with the help of the scrub nurse I proceeded with the removal of the appendix and the wound closure, this being accomplished with considerable difficulty, since the patient was making violent convulsive movements.

The pupils were widely dilated during the convulsive seizure. The blood pressure during most of the time was too high to be recorded. The highest systolic record was 280, and the diastolic pressure at that time was 150. During this interval the pulse rose to 160 to 180 and the rectal temperature rapidly rose to 104°F. As soon as the convulsion started oxygen was given under pressure and was continued until the attack ceased. A phlebotomy was performed, 600 cc. of blood being removed, and then 50 cc. of 50 per cent glucose solution and 20 cc. of 10 per cent magnesium sulfate were administered intravenously. As soon as the wound was closed, the patient was rolled on his side and 15 cc. of spinal fluid was removed; it was not under

increased pressure. Sodium amytal was called for, but was not available.

At the end of the convulsion, ice bags were applied and the temperature started to drop, as did the pulse and blood pressure. The last blood pressure reading in the operating room, 20 minutes after the convulsion ceased, was 165/85. The blood pressure continued to drop, and 1 hour later it was 90/28. At that time 250 cc of plasma and 5 cc of coramine were given. The blood pressure rose rapidly to within normal limits, and thereafter the patient continued to show steady improvement. He regained consciousness only slightly more slowly than one would expect of a patient who had received a general anesthetic, and by morning showed no neurologic changes and felt well. The only complication was a small wound abscess, which healed rapidly. The last blood pressure reading, taken on the 16th postoperative day, was 120/78. Two months postoperatively the patient was back at work as a surveyor feeling quite well.

The anesthetic consisted of a small amount of nitrous oxide and about 45 cc of ether, which seemed to be tolerated well. The spinal fluid showed a weakly positive Pandy reaction, a protein level of 30 mg per 100 cc, a normal cell count, a negative Wassermann reaction and a colloidal gold curve of 2211100000.

It was impossible to determine a cause-and-effect relation in this case. There is no explanation for the rise in the blood pressure to so high a level, much higher than that seen after violent physical exertion or even after therapeutic convulsions.¹⁵ Probably the duration of the convulsion had a great deal to do with the high readings. Perhaps the blood pressure mounts to high levels in such cases and has not happened to be recorded.

As for the increase in body temperature, this could have come about as the result of the muscular exertion. Perhaps, however, the temperature rose during the early part of the operation, unknown to us, and after reaching a certain level contributed to the development of the convulsion. In any event, this case illustrates how complete recovery may follow such a violent episode. It is impossible to state to what extent the intravenous glucose and magnesium sulfate assisted in recovery.

For an extensive bibliography on the subject of anesthetic convulsions the reader should consult the article by Ray and Marshall.⁹

SUMMARY

Convulsions occurring during general anesthesia are not rare, and may occur with the use of any general inhalation anesthetic.

The etiology is unknown, although youth, the presence of fever and hot, humid external surroundings may be important factors.

The mortality rate is 20 to 25 per cent.

Treatment must be immediate and energetic, the use of oxygen and intravenous barbiturates being particularly important.

That one can survive a violent convulsion and extreme hypertension without aftereffects is shown by the case reported.

LEWIS S. PILCHER, M.D.*

NEWTON, MASSACHUSETTS

THERE are few reported cases in the medical literature of the formation of large calculi in the appendix. The two largest appendiceal calculi known are the one reported by Packard¹ in

FIGURE 1. Roentgenogram of Abdomen, with a Catheter in the Right Ureter, Showing the Large Calcified Mass in the Right Pelvis.

1921, measuring 1.0 by 2.0 by 4.0 cm., and the one reported by Bunch and Adcock² in 1939, measuring 2.75 cm. in each direction. The calculus in the case reported here also measured 2.75 cm. in diameter. So far as can be determined, these 3 cases are the only ones of true calculi of such large size found in the appendix.

The mechanism of calculus formation in the appendix is probably similar to that in the gall bladder, with chronic partial obstruction of the appendix,

stagnation of the retained appendiceal secretions and gradual formation and calcification of the mass centering around a dried-out fecal concretion. The rarity of fully formed calculi in the appendix may be due to the fact that in most cases the irritation and obstruction produced by the original fecal concretion set up a circulatory disturbance in the appendix, resulting in strangulation and gangrene at an early stage before a calculus has a chance to form.

The history of the case reported below was particularly interesting because there were so few early symptoms in spite of the fact that the calculus must have been forming in the appendix for a long period of time.

CASE REPORT

H. S., a 34-year-old man, entered the Newton Hospital complaining of pain in the lower back and the right lower quadrant of the abdomen for 2 weeks. The pain in the back was dull and steady, and on subsequent questioning the patient admitted that he had had some pain in that region for a long time, but this was mild and was always attributed to fatigue. The pain in the abdomen, which was what brought him to the hospital, was intermittent, with recurrent, severe, colicky exacerbations. Between the attacks of colic the pain was dull and constant. During the 2 weeks of acute symptoms, there were considerable anorexia and some nausea, but no acute vomiting.

Physical examination on admission revealed slight localized tenderness in the right lower quadrant but no protective spasm. The blood and urine were normal. Since the history was highly suggestive of a right ureteral calculus, cystoscopy and pyelograms were done. These showed a large calcified shadow several centimeters in diameter in the right pelvis adjacent but anterior to the right ureter (Fig. 1). There were several other calcified shadows higher in the right abdomen. A diagnosis was made of calcified, mesenteric lymph nodes. It was believed that the large calcified shadow in the right pelvis was probably also a calcified node, which because of its large size was causing the pain. Operation was therefore advised.

At operation, while waiting for the anesthetist to put the patient in Trendelenburg position, it was decided to look at the appendix. When the appendix was delivered, it was at first thought that it contained a mucocele, and it was difficult to believe there was such a large stone present until the appendix had been opened. The illustrations (Figs. 2, 3 and 4) indicate better than any verbal description the size, character and location of the calculus.

Further exploration of the abdomen showed many large calcified lymph nodes in the mesentery of the cecum and the ileum, as noted by x-ray. No definite relation could be determined between these nodes and the calculus in the appendix, except that it was assumed that the patient had a greater than average tendency to form calcium deposits. Tests of calcium and parathyroid metabolism showed no abnormality. There was no evidence of bony decalcification. There were no renal or gall-bladder calculi.

The most interesting feature of the specimen was that in spite of the marked distention of the appendix by the stone, which was situated at the proximal end of the appendix and completely obstructed it, there was no enlargement of the tip

*Member of the Surgical Service, Newton Hospital (on leave of absence).

increased pressure. Sodium amytal was called for, but was not available.

At the end of the convulsion, ice bags were applied and the temperature started to drop, as did the pulse and blood pressure. The last blood pressure reading in the operating room, 20 minutes after the convulsion ceased, was 165/85. The blood pressure continued to drop, and 1 hour later it was 90/28. At that time 250 cc. of plasma and 5 cc. of coramine were given. The blood pressure rose rapidly to within normal limits, and thereafter the patient continued to show steady improvement. He regained consciousness only slightly more slowly than one would expect of a patient who had received a general anesthetic, and by morning showed no neurologic changes and felt well. The only complication was a small wound abscess, which healed rapidly. The last blood pressure reading, taken on the 16th postoperative day, was 120/78. Two months postoperatively the patient was back at work as a surveyor feeling quite well.

The anesthetic consisted of a small amount of nitrous oxide and about 45 cc. of ether, which seemed to be tolerated well. The spinal fluid showed a weakly positive Pandy reaction, a protein level of 30 mg. per 100 cc., a normal cell count, a negative Wassermann reaction and a colloidal gold curve of 2211100000.

It was impossible to determine a cause-and-effect relation in this case. There is no explanation for the rise in the blood pressure to so high a level, much higher than that seen after violent physical exertion or even after therapeutic convulsions.¹⁵ Probably the duration of the convulsion had a great deal to do with the high readings. Perhaps the blood pressure mounts to high levels in such cases and has not happened to be recorded.

As for the increase in body temperature, this could have come about as the result of the muscular exertion. Perhaps, however, the temperature rose during the early part of the operation, unknown to us, and after reaching a certain level contributed to the development of the convulsion. In any event, this case illustrates how complete recovery may follow such a violent episode. It is impossible to state to what extent the intravenous glucose and magnesium sulfate assisted in recovery.

For an extensive bibliography on the subject of anesthetic convulsions the reader should consult the article by Ray and Marshall.⁹

SUMMARY

Convulsions occurring during general anesthesia are not rare, and may occur with the use of any general inhalation anesthetic.

The etiology is unknown, although youth, the presence of fever and hot, humid external surroundings may be important factors.

The mortality rate is 20 to 25 per cent.

Treatment must be immediate and energetic, the use of oxygen and intravenous barbiturates being particularly important.

That one can survive a violent convulsion and extreme hypertension without aftereffects is shown by the case reported.

SUMMARY

A case of giant calculus of the appendix is reported. It is believed that this is the third calculus of such size in the appendix to be reported in the literature. This calculus was particularly interesting because it was present in the proximal instead of the distal end of the appendix and caused marked

obstruction and distention of the proximal half of the appendix without producing symptoms of appendicitis.

MEDICAL PROGRESS

ABDOMINAL SURGERY

ARTHUR W. ALLEN, M.D.*

BOSTON

ADVANCES in abdominal surgery during the past year have been evaluated. Many of the papers relate to the surgery of trauma and these will not be taken into consideration except when such information may be applicable to problems of civil practice. All reports cannot be included, but many of the timely subjects will be discussed.

GENERAL CONSIDERATIONS

Anesthesia

Arrowood and Foldes¹ have modified Lemmon's² method of continuous spinal anesthesia. These authors report the use of a continuous-drop method of maintaining spinal anesthesia in approximately 40 cases. A recent personal communication reveals that over 60 patients have been anesthetized by this technic. Anesthesia is established with the usual 2.5 per cent novocain solution intrathecally, and the needle is left in place and connected to a gravity bottle containing 0.5 per cent novocain solution. Depending on the type of patient and the level of anesthesia desired, from 4 to 8 drops of the weak solution is allowed to enter the spinal canal each minute. No complications arose in any case. The maximum duration of anesthesia was six hours, with a total of 150 cc. of the solution used. Approximately 5 per cent of the cases were considered unsatisfactory due to technical errors. The method is particularly suitable for bad-risk patients and is useful when the operation takes longer than planned. The authors found that unanesthetized patients can be given from 12 to 20 drops of physiologic saline solution a minute without ill effect and without a significant rise in the intraspinal pressure; this is twice the rate of administration required for the anesthetic agent.

I have operated on patients under this type of continuous-drop novocain spinal anesthesia. It has definite advantages over the fractional method in

that there is no interval between doses. Furthermore, with the latter method the surgeon and the anesthetist are often unaware that the anesthesia has worn off until the patient moves or violently strains or protests. The patient under the new modification remains quiet and comfortable without interruption throughout the procedure.

Early Postoperative Ambulation

This method of handling patients will increase in popularity now that the use of nonabsorbable suture material has been found to result in little or no lag period in wound healing.³ It appears that fine steel wire, nylon, cotton and silk cause so little reaction in sutured tissues that there is little evidence of the so-called "weak stage" of the suture lines that frequently occurs when catgut is used.

Rickles⁴ reports the results on 146 patients observed at the Charity Hospital in New Orleans. Ninety-eight patients without peritonitis were allowed to walk on the first postoperative day following celiotomy. Eighty-seven patients who had had appendectomies through transverse incisions were allowed home on the third day, returning on the sixth day for the removal of sutures. Patients with peritonitis and those in whom the drainage of an abscess was necessary were allowed up after the danger from intraperitoneal inflammation had passed. Patients operated on for inguinal hernia were allowed to walk on the first day postoperative, and those with ventral hernia on the second. All wounds were sutured with cotton, and all healed by primary intention. There were no disruptions, and no hernias developed in the scars during one year of follow-up. None of the patients required catheterization, and only 3 needed enemas.

Powers⁵ reports on the advantages of early rising in 100 cases. The results were as good as those in a control group so far as wound healing and lack of complications are concerned. There was no decrease in postoperative thrombophlebitis in his ambula-

FIGURE 3. Roentgenogram of the Appendix, Showing the Shadow of the Calculus.

supposed to follow obstruction of the proximal portion. This was undoubtedly due to the fact that

curred without producing more pronounced symptoms. The only conclusion of general interest to

FIGURE 4. Photograph of the Sectioned Stone and Appendix. Note the roughly concentric structure of the stone and the hypertrophied mucosa in the distal half of the appendix.

the calculus enlarged very gradually and caused no acute embarrassment of the circulation of blood or lymph. It is nevertheless difficult to understand

be drawn from this fact is that simple obstruction of the appendix is not by itself the complete answer to the etiology of acute appendicitis.

Small-Bowel Obstruction

Grimson and Hodge¹¹ corroborate the experience of Folley¹² that Miller-Abbott intubation is often satisfactory as a definitive method of treatment for acute small-bowel obstruction. No time limit need be set for operative interference if the patient does well on the conservative regimen. In 7 cases so treated, 4 were symptom-free from three months to two years without surgery.

It is important to be alert for localized tenderness and maintained or developing leukocytosis, which indicate a gangrenous segment. In my opinion, better results are obtained if surgery is undertaken before gangrenous areas develop or, if already present, before perforation takes place. Equivocal cases should be explored as soon as decompression is under way and the patient's condition is stabilized. The safety of surgery within twenty-four hours after onset, as pointed out by McKittrick and Sarris,¹³ cannot be ignored.

NEOPLASMS OF ABDOMINAL WALL

These are discussed by Pack and Ehrlich¹⁴ in a review of 470 cases treated in the Memorial Hospital, New York City. They classify 391 neoplastic lesions as follows: benign neoplasm, 242; primary malignant neoplasm, 63; metastatic malignant neoplasm, 64; and lymphoma, 22. Of the 79 lesions termed non-neoplastic, 24 were cysts, 31 were inflammatory, and 24 were miscellaneous. The lymphatic spread from all neoplasms of the anterior abdominal wall is similar to that of those starting in the umbilical region. Chronic draining sinuses were a frequent source of cancerous degeneration. They call attention to the so-called "Kangri-burn" epidermoid cancer, which is well known in certain Japanese districts where an earthenware bowl containing burning charcoal is worn next to the skin of the abdominal wall as a method of maintaining warmth. Other apparent sources of epidermoid carcinoma were psoriasis, radiation dermatitis and arsenical dermatitis. Of the 63 primary malignant neoplasms, 25 were carcinoma, 30 sarcoma, and 8 melanoma. They also report 17 cases of desmoid tumors and give an excellent description of this pathologic process. Many of their desmoids had had inadequate removal elsewhere.

HERNIA

Cutler and Scott¹⁵ report 4 cases of acute small-bowel obstruction from transmesenteric hernia observed at the Children's Hospital in Boston. They have collected 46 additional cases from the literature and state that this type accounts for 11 per cent of all intra-abdominal hernias. The mortality in 50 cases was 38 per cent, although 3 of their 4 patients recovered. The majority of these hernias occurred through developmental defects in the

mesentery, although a few were thought to be due to inflammatory processes and trauma.

Jens¹⁶ reports a study of 100 patients with strangulated femoral hernia who were admitted to one institution in a five-year period. The average age of these patients was sixty-three years. Two thirds were beyond the sixth decade, and three fourths of the patients were women. Forty-two per cent gave no previous history of hernia. Strangulation was ushered in by pain and vomiting of from three hours' to fourteen days' duration in 84 per cent of the cases. Pain was not admitted by 2 of 3 patients having nonviable bowel. Pain was most frequent in the midabdomen (65 per cent), and in all these cases there was omentum or small bowel, or both these structures, in the sac. Pain at the site of hernia was present in 26 cases. It was low abdominal and colicky in nature in 7 per cent, and epigastric in 4 per cent. Tenderness over the site of the hernia was elicited or recorded in only 21 cases. Seven of the entire group were Richter's hernia. Twelve of 20 cases with gangrenous bowel required resection, with a mortality rate of 66 per cent. Two cases with exteriorized gangrenous intestine died. The over-all mortality for the entire series was 14 per cent.

White¹⁷ calls attention to the satisfactory results obtained from simple herniotomy under local novocain anesthesia in the bad-risk patient with strangulated umbilical hernia. Analysis of records of radical repair as an emergency measure revealed a high mortality rate. The dangers of radical cure in this group of patients as an operation of election are also stressed.

Burton¹⁸ emphasizes the better results obtained by autogenous fascial repair in inguinal hernia. In 385 cases repaired by the Gallie method, there were 0.9 per cent recurrences. In 132 cases repaired by the McArthur method, there were 4.5 per cent recurrences. There were 3 cases of testicular atrophy in the larger group. He depicts an ingenious foot sandal, with a canvas strap attached, to maintain the leg in inversion while the fascia lata is being procured.

Ryan¹⁹ corroborates the results obtained by McCloskey and Lehman²⁰ in the routine use of the McArthur type of repair in inguinal hernia. He advocates cotton sutures to reinforce the wound and uses the Bisgard needle to carry the fascial strip. Ninety-two cases were followed without evidence of recurrence.

A combination of the McArthur and the Halstead I operations, employing fine silk or cotton sutures, has been the minimum standard repair used in adults on the East Surgical Service of the Massachusetts General Hospital for a number of years. It has given extremely low rates of infection and of recurrence in a large group of patients operated on by the resident staff. Alternate cases have been ambulated on the first postoperative day with no

tory cases. He emphasizes the beneficial results of early ambulation and finds no contraindications to its use.

Shorter⁶ emphasizes early rehabilitation in abdominal surgery and calls attention to the low incidence of chest complications and the reduction in circulatory disturbances, as well as to the maintenance of muscle and joint tone and the beneficial effect on morale. Patients not suitable for early ambulation were given exercises in bed.

At the Massachusetts General Hospital we have been interested in the good effects of early ambulation, long used in the aged but only in recent years applied to other patients. The danger of wound infection is apparently increased by early rising, but this has not been serious in nature. There appears to be little reduction in thrombosis of the leg veins in ambulatory patients as compared with a control group. So far, there has been no evidence of increased hernia-in-scar, and wound disruption has not occurred. The patient handled in this manner remains in good physical condition and is able to resume his usual activities at an early date.

Sulfonamides

The use of sulfonamides in abdominal surgery is challenged by Rea,⁷ who states that a recent review of the literature reveals that many reports are misleading. The experience of the operator using modern methods of preparation, anesthesia and aftercare makes comparative data based on earlier cases open to question. He points out that only alternate cases treated by the same surgeon under the same conditions at the same season of the year with and without sulfonamides would reveal their true value. Experimental work is cited to support the better effect of sulfonamides as a preventive measure to infection rather than a curative one after suppuration has been well established. He was unable to observe that the intraperitoneal use of sulfonamides influences the outcome in suppurative peritonitis of enteric origin in experimental animals, and is of the opinion that pus inactivates the sulfonamide.

It is my opinion that the intravenous use of sulfadiazine is superior in its effect and perhaps safer than the intraperitoneal use of sulfonamides. The former drug can be continued by mouth as soon as adequate fluids can be given by this route. Rare cases in which renal and ureteral crystals are formed must be kept in mind and properly treated.

Glove Powder

Talcum is generally used as a glove powder, but this substance is criticized by Seelig, Verda and Kidd.⁸ These authors point out the danger of producing a serious adhesive, granulomatous foreign-body reaction if any talcum powder is allowed to

come in contact with peritoneal surfaces. If too much powder is used in the glove and the finger tip becomes punctured, great damage may be done from a small amount of talcum spilled into the peritoneal cavity. They found after much experimentation that a powder (210 to 270 mesh) of potassium bitartrate (cream of tartar) was harmless in the peritoneal cavity of experimental animals. This material shortened the life of rubber gloves by one half.

In trying this substitute for talcum at the Massachusetts General Hospital, we have found that the glove is often sticky and difficult to get on. It seems necessary to find a better powder than potassium bitartrate before it can be satisfactorily used. Until a suitable material can be found, one can either use wet gloves or reduce the danger to a minimum by using talcum sparingly inside the gloves, and washing the outside after putting them on.

Management of Penetrating Wounds

Zininger⁹ gives an excellent outline for the evaluation and management of penetrating wounds of the abdomen. First of all, the degree of shock must be determined, and this combated by plasma followed by blood. Only the patient with obvious continued internal bleeding should be operated on before shock is controlled. The second consideration is the nature of the injury, its extent and the direction of the penetrating missile. This is often best determined by a scout roentgen film if there is no wound of exit. From the location of the foreign body on the film and the point of entry, the structures penetrated can be surmised. The third important observation is whether or not there is evidence of peritoneal irritation. He prefers intratracheal cyclopropane anesthesia and, if the intestine has been penetrated, advises the use of 5 to 10 gm. of sulfanilamide intraperitoneally as well as intravenous sulfadiazine. He is of the opinion that through-and-through closure of the abdominal wall with silver wire is the method of choice in these cases.

Noble¹⁰ proposes an ingenious method of treating old wounds of the small intestine by plication of one loop of gut to its nearest segment. This is carried out through the entire small bowel. He advises hourly doses of Pitressin and claims recovery in 90 per cent of a large series of cases so treated. He believes that local closure of perforations leads to stasis above and between such areas of repair and that the high number of poor results under these circumstances are due to the absorption of toxins from partially obstructed segments of bowel.

One wonders whether this complete plication of the small intestine would be useful in cases of extensive adhesions with repeated episodes of small-bowel obstruction, particularly if the mesentery was such as to lend itself to repeated volvulus.

er tube. Intestinal continuity is re-established by implanting the proximal jejunum end-to-side into the distal limb at a point approximately 18 cm. from the portal fissure. These patients have had no bile leakage at the anastomotic site. There has been less evidence so far of the frequently disabling cholangitis observed after other methods of repair. Theoretically, there should be less chance of cicatricial constriction at the anastomosis and less chance of ascending cholangitis, since the lumen of the gut is large and the peristaltic current is away from the liver ducts. It will require a greater experience and a longer follow-up period to determine the actual advantages of this method, if any.

Best³⁰ calls attention to the frequency of liver-duct stones that cannot be removed surgically. He states that the incidence of such stones is about 7 per cent of patients with cholelithiasis. Although he fails to discuss the possibility that these stones will spontaneously leave the liver if the papilla of Vater is gradually dilated to a diameter slightly larger than that of the hepatic ducts, he brings out helpful information regarding flushing the biliary system before and after operation. His method is used a few days prior to exploration and about the eighth and fifteenth days postoperatively. The treatment is carried out three days in succession. On the first day, this patient is given 3 tablets of Decholin or Procholin three times a day and at bedtime, 0.6 mg. (1/100 gr.) of nitroglycerin before meals, 30 cc. of pure cream before the evening meal and at bedtime and 8 gm. of magnesium sulfate before breakfast. The second day varies only by substituting 0.6 mg. of atropine sulfate for the nitroglycerin. The third day's regimen is the same as that of the first.

I have found this method of treatment helpful in a few cases of cholangitis following common-duct reconstruction. In one case, it has been continued with more or less regularity three days each week, since symptoms of mild pain, chills, fever and itching recur if the treatment is omitted for any length of time.

Ferguson³¹ reports an ingenious method of treating chronic ascites. In a patient requiring frequent paracenteses, one of the two normal kidneys was removed and its pelvis implanted into the peritoneal cavity. This was successful only after the third operation, when the implantation was located behind the lower posterior rectus sheath where it functioned perfectly throughout one year of observation. The two previous attempts at implantation in other locations ceased to function after a while owing to plugging of the ureteral orifice with omentum and so forth. The patient voided the ascitic fluid with the urine secreted by the remaining kidney.

Pickrell and Clay³² report the successful removal of the left lobe of the liver in 3 patients, one of whom had a primary carcinoma, one a hemangioma, and one a gumma thought at the time of operation to be

a carcinoma. They have collected only 56 cases of liver lobectomy from the literature and state that no other author has reported more than a single case.

ULCER OF STOMACH AND DUODENUM

Much has been written about the importance of the ulcer problem in military personnel. Tidy³³ makes an exhaustive report on the situation in the British army. Having analyzed 800 army cases, he found that 58 per cent of all patients admitted with dyspepsia were found to have ulcer. He stresses the need for accurate diagnosis and believes that soldiers with ulcer should have duty compatible with a suitable dietary regimen. Those with functional disorders should be diagnosed early and sent to regular duty before they become neurotic about their symptoms. He states that if the diagnosis of ulcer was incorrectly made on a man with a functional disturbance, it became difficult to overcome this error. He claims that there is no evidence to support the theory that ulcer is more liable to develop in soldiers than in civilians. Eighty per cent of all army personnel having ulcer were found to have had symptoms for an average of seven years, dating back into civil life.

This accurately corresponds with the data on this subject reported by Rush³⁴ regarding American soldiers in the combat zone. He agrees that soldiers with ulcer are not suitable for combat duty. This is in accord with the report by Logan³⁵ regarding men in the Navy.

Rook³⁶ studied this situation in the Royal Air Force. He selected 194 cases and followed them for two and a half years. Only half these men were eventually able to do flying duty. The higher the rank, the more the likelihood that the man would be able to carry on. Of the whole group, two thirds are still in service and one third have been invalided. He claims that neither the length of the history nor any of the criteria of diagnosis appear to offer guidance whether or not an airman after treatment for ulcer is likely to withstand service life.

In 200 dyspeptic soldiers, Guyer³⁷ compares the diagnosis by means of fluoroscopy and gastroscopy. The findings were normal by both methods in about 40 per cent of the cases. Roentgenologic studies were normal in the cases (nearly 31 per cent) found to have gastritis gastroscopically. Duodenal or gastric ulcer was found by one or both methods in only 16.5 per cent of the group studied.

Spicer, Stewart and Winsor³⁸ report that perforated ulcer increased from approximately 25 to 35 per cent during the London Blitz. This fell to normal or below after the air raids ceased. The authors attempt to show the effect of anxiety on ulcer activity. They fail to take into consideration the physical hardships of air-raid shelters, with the almost certain change in dietary habits.

serious complications and with much less invalidism than that in a control group. The early risers have been kept in the hospital until the tenth post-operative day, whereas those treated for twelve days with recumbency have averaged fifteen days of hospitalization.

BILIARY SYSTEM

White²¹ gives an excellent presentation on the differential diagnosis in jaundice. In 175 cases, the proved error in diagnosis was 8 per cent; half these were due to overlooking small or latent tumors. He states that there is too great a tendency to make a diagnosis of portal cirrhosis in the alcoholic patient when the obstruction is actually due to cancer. Partial obstruction proved to be caused by benign lesions in 91 per cent of the cases, and complete obstruction was due to cancer in 96 per cent. This, I believe, is not the generally accepted rule and probably is the result of including a large number of cases of toxic hepatitis and biliary cirrhosis with those of obstructive jaundice. White believes that hurried exploration is seldom justified and that many of the cases can be correctly diagnosed by sufficient time and study. The easiest cases to diagnose were those with toxic and infectious hepatitis, those with complete external obstruction and those with hemolytic jaundice. Patients with multiple lesions, those who were extremely ill and on whom complete study was not possible and those with tumors of the liver and bile passages offered the greatest diagnostic difficulties. Surgery undertaken on the diagnosis of obstructive jaundice in patients suffering from hepatitis gave a high mortality rate.

Benedict²² has demonstrated the value of peritoneoscopy and biopsy of the liver for diagnosis in equivocal cases. In most cases, the pathologist can make a definite diagnosis of obstructive jaundice or hepatitis from the biopsy specimen. This method should be used earlier and oftener, since the opportunity for radical cure by the Whipple operation in cancer of the ampulla of Vater or head of the pancreas may be lost if delayed too long.

Truesdell²³ routinely palpated the gall bladder in 500 women undergoing abdominal pelvic surgery and found 50 cases of gallstones. A careful review of the history revealed that only 2 of these patients had had no symptoms referable to the gall bladder. Of these 50 patients, 8 died more or less promptly, 6 received immediate cholecystectomy, 12 sooner or later returned for operation, 12 were lost sight of, and 12 remained under observation.

Robertson and Dochat,²⁴ in a collective review, have challenged the usually accepted viewpoint that women who have borne children are more apt to have gallstones than are spinsters. They estimated that 79.25 per cent of all women have borne children; this figure is practically identical with the percentage of parous women with gallstones re-

ported by thirty-four authors — 79.6 per cent 11,154 of 14,016. They admit that gallstones two or three times as common in women as in men but refute the belief that pregnancy plays any part in their development.

Bearse²⁵ analyzed 253 consecutive persons treated cases of gallstones. Thirty-nine per cent of his patients had complications from the stones at the time of operation. Twenty-seven per cent had acute inflammation of the gall bladder, including empyema, gangrene and perforation. Twelve per cent had common-duct stones. Four per cent had acute pancreatitis, and 3 patients had carcinoma of the gall bladder. There were 16 postoperative deaths in the series, only 3 of which were attributable to delay in surgical treatment. He deduces that delay may be justifiable in the absence of complications but that when complications are present prompt treatment is imperative.

Cowley and Harkins²⁶ found only 25 cases of perforation of the gall bladder in 2750 patients with cholecystic disease treated at the Henry Ford Hospital in Detroit in twenty-two years. They admit that the differential diagnosis of acute cholecystitis without and with perforation is difficult and uncertain. They are of the opinion that operation at the election between attacks should be stressed rather than early operation after acute symptoms develop.

Finney²⁷ analyzed all cases of carcinoma of the gall bladder treated at the Union Memorial Hospital in Baltimore and substantiates the general opinion that all these patients had gallstones. He stresses the danger of advising good-risk patients with gallstones against operation of election, even if their symptoms are minimal. The unsatisfactory results of operation after cancer develops strengthen his argument.

Walton,²⁸ in a fascinating treatise, calls attention to the great importance of careful biliary-tract surgery. Anomalies of the bile ducts and blood supply are far more frequent than usually thought. Injuries due to anomalies or to carelessness often result in fatalities, and when the patient survives, it may be only for a short period of invalidism. He reviews the literature regarding the various methods of establishing continuity between the injured bile duct and the gastrointestinal tract. He reports on his own experience with a method of a valve-like anastomosis between the hepatic duct and the duodenum. As in practically all other such reports, the results leave much to be desired.

I²⁹ have recently reported the immediate results of re-establishing continuity between the bile duct and the gastrointestinal tract by a new method which was first mentioned in the progress report for 1940. Eight patients have been treated by implantation of the hepatic duct into the distal transected end of the jejunum 30 cm. from the ligament of Treitz. The cut end is inverted and the anastomosis accomplished over a

er tube. Intestinal continuity is re-established by implanting the proximal jejunum end-to-side into the distal limb at a point approximately 18 cm. from the portal fissure. These patients have had no bile leakage at the anastomotic site. There has been less evidence so far of the frequently disabling cholangitis observed after other methods of repair. Theoretically, there should be less chance of cicatricial constriction at the anastomosis and less chance of ascending cholangitis, since the lumen of the gut is large and the peristaltic current is away from the liver ducts. It will require a greater experience and a longer follow-up period to determine the actual advantages of this method, if any.

Best³⁰ calls attention to the frequency of liver-duct stones that cannot be removed surgically. He states that the incidence of such stones is about 7 per cent of patients with cholelithiasis. Although he fails to discuss the possibility that these stones will spontaneously leave the liver if the papilla of Vater is gradually dilated to a diameter slightly larger than that of the hepatic ducts, he brings out helpful information regarding flushing the biliary system before and after operation. His method is used a few days prior to exploration and about the eighth and fifteenth days postoperatively. The treatment is carried out three days in succession. On the first day, this patient is given 3 tablets of Decholin or Procholin three times a day and at bedtime, 0.6 mg. (1/100 gr.) of nitroglycerin before meals, 30 cc. of pure cream before the evening meal and at bedtime and 8 gm. of magnesium sulfate before breakfast. The second day varies only by substituting 0.6 mg. of atropine sulfate for the nitroglycerin. The third day's regimen is the same as that of the first.

I have found this method of treatment helpful in a few cases of cholangitis following common-duct reconstruction. In one case, it has been continued with more or less regularity three days each week, since symptoms of mild pain, chills, fever and itching recur if the treatment is omitted for any length of time.

Ferguson³¹ reports an ingenious method of treating chronic ascites. In a patient requiring frequent paracenteses, one of the two normal kidneys was removed and its pelvis implanted into the peritoneal cavity. This was successful only after the third operation, when the implantation was located behind the lower posterior rectus sheath where it functioned perfectly throughout one year of observation. The two previous attempts at implantation in other locations ceased to function after a while owing to plugging of the ureteral orifice with omentum and so forth. The patient voided the ascitic fluid with the urine secreted by the remaining kidney.

Pickrell and Clay³² report the successful removal of the left lobe of the liver in 3 patients, one of whom had a primary carcinoma, one a hemangioma, and one a gumma thought at the time of operation to be

a carcinoma. They have collected only 56 cases of liver lobectomy from the literature and state that no other author has reported more than a single case.

ULCER OF STOMACH AND DUODENUM

Much has been written about the importance of the ulcer problem in military personnel. Tidy³³ makes an exhaustive report on the situation in the British army. Having analyzed 800 army cases, he found that 58 per cent of all patients admitted with dyspepsia were found to have ulcer. He stresses the need for accurate diagnosis and believes that soldiers with ulcer should have duty compatible with a suitable dietary regimen. Those with functional disorders should be diagnosed early and sent to regular duty before they become neurotic about their symptoms. He states that if the diagnosis of ulcer was incorrectly made on a man with a functional disturbance, it became difficult to overcome this error. He claims that there is no evidence to support the theory that ulcer is more liable to develop in soldiers than in civilians. Eighty per cent of all army personnel having ulcer were found to have had symptoms for an average of seven years, dating back into civil life.

This accurately corresponds with the data on this subject reported by Rush³⁴ regarding American soldiers in the combat zone. He agrees that soldiers with ulcer are not suitable for combat duty. This is in accord with the report by Logan³⁵ regarding men in the Navy.

Rook³⁶ studied this situation in the Royal Air Force. He selected 194 cases and followed them for two and a half years. Only half these men were eventually able to do flying duty. The higher the rank, the more the likelihood that the man would be able to carry on. Of the whole group, two thirds are still in service and one third have been invalided. He claims that neither the length of the history nor any of the criteria of diagnosis appear to offer guidance whether or not an airman after treatment for ulcer is likely to withstand service life.

In 200 dyspeptic soldiers, Guyer³⁷ compares the diagnosis by means of fluoroscopy and gastroscopy. The findings were normal by both methods in about 40 per cent of the cases. Roentgenologic studies were normal in the cases (nearly 31 per cent) found to have gastritis gastroscopically. Duodenal or gastric ulcer was found by one or both methods in only 16.5 per cent of the group studied.

Spicer, Stewart and Winsor³⁸ report that perforated ulcer increased from approximately 25 to 35 per cent during the London Blitz. This fell to normal or below after the air raids ceased. The authors attempt to show the effect of anxiety on ulcer activity. They fail to take into consideration the physical hardships of air-raid shelters, with the almost certain change in dietary habits.

Raw³⁹ analyzed 1052 cases of perforated ulcer occurring from 1937 to 1941 in England and showed a yearly rise from 181 cases in 1937 to 251 in 1941. The average age of the patients was forty-two years, which was obviously influenced by the younger citizens being in military service. The death rate under the age of forty-two was 7.6 per cent, whereas over forty-two it was 21.3 per cent. He calls attention to the fact that delay in operation was more frequent in women than in men, owing to the fact that in the former the acute onset was incorrectly interpreted as due to gallstone colic. The average delay in the women of this group was eighteen hours, with a shocking mortality rate. The author agrees that the closure should be made as early as possible with minimal surgery and with gentleness but reasonable speed.

Wakeley⁴⁰ compares a group of 102 civilians and 103 naval personnel with perforated ulcer. The civilians averaged forty-six years of age, with a mortality rate of 20 per cent, and the naval group averaged thirty-two years of age, with a mortality rate of 8 per cent. He believes that the Royal Navy, having standardized its treatment by immediate gastric suction, early closure and sulfanilamide therapy, may reduce the mortality rate to 1 per cent.

Walters and Butt⁴¹ make a strong plea for radical surgery in the personnel of the United States Navy with duodenal ulcer. They point out that the operative mortality is very low and that 85 per cent of the patients so treated were returned to active duty. A comparable analysis of a much larger group treated medically showed that only 50 per cent were able to return to active duty. These authors believe that many valuable men can be retained in service after proper subtotal gastric resection.

Weinstein et al.⁴² have completed some experimental work on animals and operated on 6 patients for ulcer by various incomplete interruptions of the vagus nerves. They have apparently done these operations from below the diaphragm and illustrate how difficult, if not impossible, it is to completely section the vagus nerves by this route. In none of their cases was the secretion of the stomach or the acidity influenced by partial vagotomy.

Dragstedt and Owens⁴³ have made a preliminary report on transthoracic interruption of the vagus nerves in ulcer of the stomach and duodenum. It appears that their experimental work and early cases have been further substantiated by a later report on 18 clinical cases.⁴⁴ In all these, the patients were relieved of their ulcer symptoms and the ulcers were shown by roentgenographic studies to be healed. There seems to be a definite reduction in gastric secretion and acidity after this procedure.

Moore⁴⁵ has accomplished transthoracic vagus interruption in 3 patients at the Massachusetts General Hospital. These were carefully selected as desirable subjects for the procedure and were not

thought suitable for subtotal gastrectomy. The patients are, at this time, greatly improved and are being carefully followed.

CANCER OF STOMACH

St. John, Swenson and Harvey⁴⁶ examined fluoroscopically 2413 patients beyond the age of forty coming to the outpatient department of the Presbyterian Hospital in New York City for other than gastrointestinal complaints. Three of these were found to have unsuspected malignancy of the stomach — a rate of 1.24 per 1000. In 528, functional and organic lesions other than cancer were discovered. Ninety of these patients had abnormalities within the thorax. The feasibility of this type of examination is discussed. Much depends on the experience of the roentgenologist, and even under ideal circumstances, such studies are unreliable. Many cases of advanced cancer of the stomach have been found within a few weeks after a negative observation. It seems improbable that the high incidence of deaths from cancer of the stomach can be materially lowered by such routine roentgenographic examinations.

Bisgard⁴⁷ emphasizes the interrelation of gastric ulceration and cancer of the stomach. The differential diagnosis between ulcer and cancer of the stomach is admittedly difficult and often impossible.⁴⁸ Ulcers that appear benign gastroscopically and roentgenologically are often malignant. These lesions appear, at times, to diminish in size, and symptoms improve under treatment, the patient returning, often too late, with obvious cancer of the stomach. The patient with gastric ulcer must be kept under close observation, and delay in surgical interference must be reduced to a minimum. The end results of gastric resection for ulcers that appear benign but prove to be malignant are twice as good as those when the operation is undertaken for obvious clinical cancer. Bisgard further substantiates the fact that gastrectomy is safer for gastric ulcer than for duodenal ulcer and that the results of this type of treatment are more satisfactory than are those of conservative management.

Feldman⁴⁹ discusses the life cycle of carcinoma of the stomach. He followed 3 patients over a period of years who had what appeared to be benign gastric ulcer with remissions. Two had relatively low gastric acidity, and the other one had hyperacidity. All these patients eventually developed pyloric obstruction that proved to be due to inoperable cancer of the stomach. He warns against the false security of negative roentgenologic examinations and believes that narrowing of the pylorus may be significant in the absence of a demonstrable tumor. Emphasis is placed on the clinical picture. If the patient is progressively getting worse, frequent observations are necessary until the diagnosis is established.

INTESTINAL DIVERTICULUMS

Warren and Emery⁵⁰ found 103 cases of diverticulum of the duodenum at the Peter Bent Brigham Hospital in Boston over a period of twenty-seven years. This represented an incidence of 2.3 per cent of cases showing roentgenologic evidence of gastrointestinal disease. The average age of the patient was fifty-eight years; 39 were in men and 64 were in women, a reversal of the sex ratio for other duodenal lesions. The size of the diverticulum varied from 0.5 to 6 cm. in diameter; 9 per cent were in the first, 65 per cent in the second and 15 per cent in the third portion of the duodenum, the remainder being multiple. They call attention to a false type in the first portion and a true herniation in the second. The authors believe that many of these lesions are symptomless and that other causes for complaint, such as gallstones, ulcer and pancreatitis, should be ruled out. The treatment for the majority of cases is that used for duodenal ulcer. Only diverticula forming an abscess or failing to empty should be treated surgically.

Pearse⁵¹ presents an excellent description of the surgical management of complicated duodenal diverticula. He illustrates a method of identifying and preserving the opening of the common bile duct and the pancreatic ducts during the procedure. A portion of the neck of the sac is left, as in operations for esophageal diverticula, in order to secure an adequate inversion.

Rudder⁵² reports an interesting case of acute diverticulitis of the jejunum. His patient was a fifty-six-year-old Costa Rican farmer who gave a history of postprandial pain of two months' duration. He was hospitalized after three days of intermittent colicky nonradiating epigastric pain and vomiting. The abdomen was flat and rigid, without distention or increased peristalsis. The maximum tenderness was in the midepigastrium. The white-cell count rose from 24,000 on admission to 49,100 within a few hours. The maximum temperature was 101.2° F. The preoperative diagnosis was acute cholecystitis with perforation of the gall bladder. A large acutely inflamed diverticulum was found 45 cm. from the ligament of Treitz. This was excised, and the patient recovered uneventfully.

Young and Young⁵³ discuss diverticulitis of the colon and, by a compilation of statistics, find that 5.2 per cent of 70,572 patients examined by barium enema or at autopsy showed diverticula. In three series of cases totaling 3915 patients, 34.3 per cent showed inflammation. The majority of patients with diverticulosis can remain symptom free by proper dietary measures and bowel hygiene. They call attention to the apparent transient improvement in symptoms by barium enemas. Approximately 22 per cent of the patients with diverticulitis finally come to surgery for one or more of five reasons, that is, acute perforation with spreading peritonitis, obstruction of the sigmoid, fistula,

localized abscess and inability to rule out cancer. They obtained a history of bleeding in 26 per cent of their cases.

LYMPHOSARCOMA

McSwain and Beal⁵⁴ studied 20 cases of lymphosarcoma of the gastrointestinal tract entering the New York Hospital during a recent nine-year period. These were distributed as follows: esophagus, 1; stomach, 7; small intestine, 3; appendix, 2; and colon and rectum, 7. There were 13 males and 7 females, with ages varying from four and a half to seventy years, — the average being forty-three years. They point out that the correct diagnosis is rarely made preoperatively. Survival is influenced more by the site and extent of the process than by age or the histologic structure of the tumor. Six patients who had well-localized lesions without involved lymph nodes and were treated by excision alone were alive and free of recurrence from two to seven years. Of the 6 patients treated by radiation alone, only 2 were free of recurrence. Two patients were unable to tolerate roentgen therapy and succumbed before treatment was finished. Of the 6 patients treated by excision followed by radiation, 2 were still free of recurrence. Nine of the 20 cases were free of recurrence from one to nine and a half years after the diagnosis was established. Eight patients succumbed with an average duration of two years of life. The authors believe that the best prognosis is in patients who have lesions suitable for complete excision. Roentgen therapy should be used in all cases in which the surgeon and the pathologist are uncertain that the disease has been completely removed.

Winkelstein and Levy⁵⁵ studied 15 cases of lymphosarcoma of the intestines and believe that these tumors arise in the lymph nodes or lymph follicles of the submucosa. The mucosal gland structure is obliterated, and the submucosa and muscularis become invaded, which results in a submucosal tumefaction. Stenosis of the small intestine by the tumor is rare, but intussusception is of common occurrence. Lesions affecting the large bowel are prone to produce obstruction. These authors state that the lymph nodes were involved in all their cases. Distant metastases to the liver, spleen and kidneys occurred rarely. They call attention to a characteristic sigmoidoscopic appearance of the tumor, which appears to resemble the surface of the brain. The average age of their patients was forty-four years, and the prognosis was poor even with the best treatment, which they thought to be a combination of surgery and radiation. The typical picture was a history of distention, colicky pain and a slightly tender movable mass.

MISCELLANEOUS

Kennedy, Dixon and Weber⁵⁶ report 11 children from three to fourteen years of age treated for

Raw³⁹ analyzed 1052 cases of perforated ulcer occurring from 1937 to 1941 in England and showed a yearly rise from 181 cases in 1937 to 251 in 1941. The average age of the patients was forty-two years, which was obviously influenced by the younger citizens being in military service. CASE 31061

PRESENTATION OF CASE

A fifty-three-year-old toolmaker was admitted to the hospital with substernal pain.

The patient was well until three months prior to admission, when he noted "substernal congestion." This cleared up and he continued to work. About one month later he developed definite substernal pain. Three weeks later he was admitted to another hospital, where all x-ray examinations and studies were said to have been negative. At that time the blood pressure was "elevated." He was told to forget his pain, since no cause for it had been found. The pain continued, however, at irregular times and was not related to meals, exercise or position. It was hard for him to define it more exactly than to say it was bad and that he became fearful that something terrible might happen to him unless it was controlled. He denied cough or dyspnea. He was discharged after a few days, but severe substernal pain persisted. He consulted another physician, who gave him "electrical treatments," which seemed to make him worse. About two weeks before entry he was admitted to another hospital, where roentgenograms and other studies revealed abnormalities that could be responsible for the pain, and he was referred to this hospital for bronchoscopy. He had lost 37 pounds over a period of about three months.

About twelve years before admission he was first found to have slight hypertension. He had been worried about high blood pressure for a long time, since both his parents and two of his grandparents had had it. One brother had died of hypertension and renal failure at the age of forty-four.

Physical examination revealed a healthy-looking man showing evidence of weight loss. There was a

slight Horner's syndrome on the left. The thyroid gland was two to three times its normal size, with a nodule on the right, no bruit was audible over it. There was retromanubrial dullness over an area 8 cm. in width, and slight dullness over the left first and second interspaces. Fremitus and breath sounds were diminished over the left upper lobe. The heart sounds were regular and of fair quality. No murmurs were heard. The abdomen was soft, and no masses or organs were palpable. The femoral pulsations were equal. An examination of the larynx revealed paralysis of the left vocal cord and arytenoid.

The temperature, pulse and respirations were normal. The blood pressure was 180 to 210 systolic, 120 diastolic, and equal in both arms.

Examination of the blood showed a white-cell count of 10,900, with 70 per cent neutrophils, 16 per cent lymphocytes, 7 per cent monocytes and 7 per cent eosinophils. The hemoglobin was 13 gm. The urine had a specific gravity of 1.006, with a + test for albumin; the sediment contained occasional red cells, white cells and hyaline and granular casts. The alkaline phosphatase was 6.9 units per 100 cc. A Hinton test was negative. A phenolsulfonphthalein test showed 20 per cent dye output in fifteen minutes and 10 per cent more in thirty minutes.

By the seventh hospital day the pain had increased and required frequent injections of morphine. He said that it radiated to the midback. A fluoroscopic examination showed a pulsating mass continuous with the aorta, but the left diaphragm appeared paralyzed and showed paradoxical motion. On the tenth hospital day the pain was located about both costal margins. On the twelfth hospital day he was in severe pain, sweating and sitting on the edge of a chair; the pain had extended to the left kidney and to a slight degree into the left leg. Films of the chest revealed an area of increased density, extending from the left hilus into the midchest, that could not be separated from the hilus or the descending aorta (Fig. 1). The edge was sharply demarcated, and there seemed to be some atelectasis of the lung around it. The density pulsed with the aorta, but the descending aorta could be traced through it. The left leaf of the diaphragm was elevated and again showed paradoxical motion. The lung fields were otherwise clear.

On the morning of the thirteenth hospital day the patient suddenly coughed up 4 to 8 cc. of blood-

diagnosis. I should put the neoplasm in the bronchus of the upper lobe.

Three or four months before admission, x-ray studies were negative, which is perfectly all right for a bronchial neoplasm that is concealed in the mediastinum and therefore not seen during fluoroscopy or on the first x-ray plate. The patient then began to have signs of obstruction of the left upper lobe, with atelectasis, and associated with that he began to have signs of a sulcus tumor. He had paralysis of the recurrent laryngeal nerve on the left and paralysis of the diaphragm on the left, all of which suggest invasion of the left mediastinum. This, of course, might have been a lymphangitic type of carcinoma of the lung, in which case I could not differentiate it without seeing the x-ray films. Then the patient coughed up bloody sputum and began to get central-nervous-system signs, which could have been caused by an embolus. An infected cerebral embolus fits in well with the Jacksonian epilepsy and the high temperature. There is no suggestion of anything wrong with the heart, and nothing suggestive of a mycotic aneurysm or subacute bacterial endocarditis. The Jacksonian epilepsy and nerve palsies, however, could also have been due to a silent cerebral metastasis, with hemorrhage into it. One other reason for the diagnosis of bronchiogenic neoplasm lies in the blood phosphatase level, which is double the normal. When a carcinoma of the bronchus breaks into a pulmonary vein, the tumor is distributed all over the body. It not infrequently gets into the bones, where it usually forms an osteoclastic lesion, but there is no reason why there cannot be an osteoblastic reaction, which would give an elevated phosphatase level in the blood.

This man probably had a bronchiogenic neoplasm in the left upper bronchus, with atelectasis and possibly pneumonia or abscess behind it to account for the fever. I think that he also had metastases, probably widespread, involving bone—it is usually in the vertebrae, in spite of the negative x-ray evidence—and the right cerebral region, with slight hemorrhage into the latter. I believe that he had contracted kidneys, which produced a urine of low, fixed specific gravity, but that this was of secondary importance.

May I now see the x-ray films?

DR. CHESTER M. JONES: Does the fact that pulsation of the dorsalis pedis artery was demonstrated argue against dissecting aneurysm?

DR. AUB: Yes. I looked throughout the history for evidence of some vessel that was obstructed but could find none.

DR. WYMAN RICHARDSON: My bet is aneurysm.

DR. LAURENCE L. ROBBINS: I appreciate Dr. Aub's confidence in diagnosis by x-ray examination, because differentiation of cancer of the left-upper-lobe bronchus and aneurysm is one of the most difficult to make. I have put up the films that were done elsewhere to show the development of the

process. This is a chest examination, which was interpreted as negative. These films were taken approximately one month later, and there has been a definite change, the left diaphragm being elevated. The films that were taken at this hospital demonstrate certain things that may be of help. This is the mass in the medial portion of the left-upper-lung field that was seen and interpreted in various ways. The fluoroscopist said that he was unable to separate it from the hilus or from the aorta. These overexposed films give a rather clear picture of the entire descending portion of the aorta. There is one other finding that may be of some value; that is, you can see a small portion of the septum between the upper and the lower lobes on the left side, and it is definitely anterior to the normal position.

DR. AUB: What does that tell us?

DR. ROBBINS: That the left upper lobe is somewhat decreased in size.

DR. AUB: You are not so helpful as I thought you were going to be.

DR. JONES: Does one get laryngeal paralysis from aneurysm? Would that mean infiltration around the nerve.

DR. AUB: The nerve involvement strongly suggests neoplasm. In fact, these x-ray studies make me disagree with Dr. Richardson.

CLINICAL DIAGNOSES

Dissecting aortic aneurysm, with compression of the left-upper-lobe bronchus.
Cerebral hemorrhage, right.
Hypertensive heart disease.

DR. AUB'S DIAGNOSES

Bronchiogenic carcinoma, left upper lobe, with metastases to mediastinum, bones and right cerebrum.
Atelectasis of left upper lobe of lung (? abscess).
Nephrosclerosis.

ANATOMICAL DIAGNOSES

Oat-cell carcinoma of the lung, left upper lobe, with extension to the mediastinal structures and pericardium and with metastases to the bronchial, mediastinal and retroperitoneal lymph nodes, adrenal and thyroid glands and vertebral spine.
Cardiac hypertrophy, hypertensive type.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this patient proved that Dr. Aub was correct. This man did have a tumor involving the left upper lobe, most of it extending into the mediastinum. The mediastinal extension and involved mediastinal lymph nodes had invaded the pericardium and surrounded portions of the arch of the aorta, encroaching on the

streaked frothy sputum. A few hours later, while lying flat for dorsal-spine films, he suddenly twisted his head to the left, had convulsive movements and became cyanotic and had stertorous breathing. These films showed marked proliferative changes

FIGURE 1.

but no definite areas of erosion or destruction. The medial border of the left lung, normally lying close to the spine, was seen to be at least a centimeter away from it. Following this there was paresis of the left side.

During the next few hours he had four or five Jacksonian seizures, beginning on the left side of the face and extending to the left arm, left leg, right arm and right leg. A few were mild and terminated with the left arm. He vomited after one seizure. Between attacks there was weakness of the left arm and leg and he was irrational, restless and noisy. There was some nuchal rigidity. The pupils were equal. The fundi could not be examined. After 400 cc. of blood were removed by venesection, the blood pressure was 130 systolic, 85 diastolic. The femoral and dorsalis-pedis pulsations were equal. A lumbar puncture revealed clear colorless fluid under a high initial pressure. Following the removal of 10 cc. the final pressure was equivalent to 400 mm. of water. The temperature rapidly rose to 105°F., and the blood pressure returned to the original level. The patient continued to cry out because of pain in the back, and the left-sided paresis persisted. He became incontinent and finally died on the fifteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB: I shall not ask to see the x-ray films because I think that they would probably disclose the diagnosis.

The Horner's syndrome is extremely important if true; but it is never spoken of again, and I should like to be sure that it was really there and not a mere asymmetry.

DR. BENJAMIN CASTLEMAN: Dr. Chapman, will you tell us about that?

DR. EARLE M. CHAPMAN: There was a slight but definite Horner's syndrome.

DR. AUB: With a loss of 35 pounds of weight one has to consider an overactive thyroid gland; there is no suggestion of this except its large size. I think that retromanubrial dullness involves one of the most difficult areas in the chest for percussion, but I shall accept the statement of increased dullness to 8 cm. All the chest findings suggest that this man had collapse of the left upper lobe.

We then learn that he had paralysis of three nerves that can be involved in the mediastinum, namely, the cervical sympathetic nerves, producing a Horner's syndrome, the recurrent laryngeal nerve and the phrenic nerve.

The value for alkaline phosphatase was twice the normal. That is undoubtedly important. One does not usually observe such a finding unless there is some reasonable explanation for it.

The attacks of cyanosis and stertorous breathing were obviously thought to be due to hypertension or to cardiac failure. I do not believe that the rest of the story sounds as if he had a cardiac lesion or cardiac failure. The hypertension was such as might well precede the cerebral attacks that he had. I suppose that is the reason they bled him, but it did little good, as might have been expected.

This is an extremely difficult case. One can argue about many things that this might have been, either in the brain, in the chest or elsewhere. I think on the whole, however, that it is best to discuss only two conditions, — aneurysm of the aorta and carcinoma of the lung, — realizing that by so doing I may completely miss the diagnosis.

Did he have an aneurysm? He had an examination three months before entry and nothing abnormal was found. If he had had an aneurysm it ought to have been observed at that time. The Hinton test was negative. Under these conditions it seems unlikely to me that he had an aneurysm of the syphilitic type, but he might have had a dissecting aneurysm. The pain gradually migrated from the chest to the kidney region and down toward the pelvis, but there is no good evidence of the closing off of any peripheral blood vessels. The whole story seems to me to be much too slow and protracted for that of a dissecting aneurysm, although I admit that dissecting aneurysm appears to be a perfectly tenable diagnosis: the patient had hypertension, he was the proper age, the story is suggestive of the way the usual pain of dissecting aneurysm is distributed, and the clinical course is also suggestive.

Carcinoma starting in one of the main bronchi of the left lung, however, appears to be a much likelier

diagnosis. I should put the neoplasm in the bronchus of the upper lobe.

Three or four months before admission, x-ray studies were negative, which is perfectly all right for a bronchial neoplasm that is concealed in the mediastinum and therefore not seen during fluoroscopy or on the first x-ray plate. The patient then began to have signs of obstruction of the left upper lobe, with atelectasis, and associated with that he began to have signs of a sulcus tumor. He had paralysis of the recurrent laryngeal nerve on the left and paralysis of the diaphragm on the left, all of which suggest invasion of the left mediastinum. This, of course, might have been a lymphangitic type of carcinoma of the lung, in which case I could not differentiate it without seeing the x-ray films. Then the patient coughed up bloody sputum and began to get central-nervous-system signs, which could have been caused by an embolus. An infected cerebral embolus fits in well with the Jacksonian epilepsy and the high temperature. There is no suggestion of anything wrong with the heart, and nothing suggestive of a mycotic aneurysm or subacute bacterial endocarditis. The Jacksonian epilepsy and nerve palsies, however, could also have been due to a silent cerebral metastasis, with hemorrhage into it. One other reason for the diagnosis of bronchiogenic neoplasm lies in the blood phosphatase level, which is double the normal. When a carcinoma of the bronchus breaks into a pulmonary vein, the tumor is distributed all over the body. It not infrequently gets into the bones, where it usually forms an osteoclastic lesion, but there is no reason why there cannot be an osteoblastic reaction, which would give an elevated phosphatase level in the blood.

This man probably had a bronchiogenic neoplasm in the left upper bronchus, with atelectasis and possibly pneumonia or abscess behind it to account for the fever. I think that he also had metastases, probably widespread, involving bone—it is usually in the vertebrae, in spite of the negative x-ray evidence—and the right cerebral region, with slight hemorrhage into the latter. I believe that he had contracted kidneys, which produced a urine of low, fixed specific gravity, but that this was of secondary importance.

May I now see the x-ray films?

DR. CHESTER M. JONES: Does the fact that pulsation of the dorsalis pedis artery was demonstrated argue against dissecting aneurysm?

DR. AUB: Yes. I looked throughout the history for evidence of some vessel that was obstructed but could find none.

DR. WYMAN RICHARDSON: My bet is aneurysm.

DR. LAURENCE L. ROBBINS: I appreciate Dr. Aub's confidence in diagnosis by x-ray examination, because differentiation of cancer of the left-upper-lobe bronchus and aneurysm is one of the most difficult to make. I have put up the films that were done elsewhere to show the development of the

process. This is a chest examination, which was interpreted as negative. These films were taken approximately one month later, and there has been a definite change, the left diaphragm being elevated. The films that were taken at this hospital demonstrate certain things that may be of help. This is the mass in the medial portion of the left-upper-lung field that was seen and interpreted in various ways. The fluoroscopist said that he was unable to separate it from the hilus or from the aorta. These overexposed films give a rather clear picture of the entire descending portion of the aorta. There is one other finding that may be of some value; that is, you can see a small portion of the septum between the upper and the lower lobes on the left side, and it is definitely anterior to the normal position.

DR. AUB: What does that tell us?

DR. ROBBINS: That the left upper lobe is somewhat decreased in size.

DR. AUB: You are not so helpful as I thought you were going to be.

DR. JONES: Does one get laryngeal paralysis from aneurysm? Would that mean infiltration around the nerve.

DR. AUB: The nerve involvement strongly suggests neoplasm. In fact, these x-ray studies make me disagree with Dr. Richardson.

CLINICAL DIAGNOSES

Dissecting aortic aneurysm, with compression of the left-upper-lobe bronchus.

Cerebral hemorrhage, right.

Hypertensive heart disease.

DR. AUB'S DIAGNOSES

Bronchiogenic carcinoma, left upper lobe, with metastases to mediastinum, bones and right cerebrum.

Atelectasis of left upper lobe of lung (? abscess).
Nephrosclerosis.

ANATOMICAL DIAGNOSES

Oat-cell carcinoma of the lung, left upper lobe, with extension to the mediastinal structures and pericardium and with metastases to the bronchial, mediastinal and retroperitoneal lymph nodes, adrenal and thyroid glands and vertebral spine.

Cardiac hypertrophy, hypertensive type.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this patient proved that Dr. Aub was correct. This man did have a tumor involving the left upper lobe, most of it extending into the mediastinum. The mediastinal extension and involved mediastinal lymph nodes had invaded the pericardium and surrounded portions of the arch of the aorta, encroaching on the

phrenic nerve. The part of the upper lobe not replaced by the tumor was collapsed.

The tumor involved the bronchus to the left upper lobe and proved to be an oat-cell type of carcinoma, which is prone to surround and invade the bronchial walls with only slight intraluminal tumor, which was true here. As Dr. Aub also predicted, the vertebral spine was practically replaced by tumor and showed a great deal of osteoblastic proliferation and fibrosis, which accounted for the elevated phosphatase.

There were metastases to the adrenal and thyroid glands. The brain showed no evidence of metastasis grossly. There was a hemorrhagic lesion in the left parietal lobe, which I do not suppose accounted for the symptoms. The microscopic sections have not been finished, but grossly it did not look like a metastasis.

DR. AUB: I suppose that the hemorrhage was on a hypertensive basis.

DR. CASTLEMAN: He did have a large heart of the hypertensive type.

DR. CHAPMAN: I want to pay tribute to Dr. Aub for his astute interpretation of the findings, which led to the correct diagnosis. I learned three things from this case that were clinically important. The first is that the nerve paralyses were not caused by a dissecting aneurysm but by the cancer. The second point, which Dr. Aub brought out in interpreting the history, is that the pain was too dragged out and too long to be the pain of a dissecting aneurysm. Dr. Castleman called that to my attention when the case was autopsied. The third point is that the clinical impression should outweigh conflicting x-ray evidence that later comes into the picture.

I started out with a diagnosis of cancer of the upper lobe with obstruction to the bronchus but ended up with a diagnosis of aneurysm. I changed my opinion because when this man was fluoroscoped they said that it was an aneurysm. The appointment for a bronchoscopy was therefore canceled and a definite diagnosis of aneurysm was made. Then the patient was fluoroscoped by Dr. Schulz, who thought that the lesion was cancer; his reasons were that, although he could not differentiate the mediastinal mass, the nerve paralysis, the paralysis of the diaphragm and the separation of the lobe were strongly in favor of cancer of the lung root.

DR. CASTLEMAN: I do not believe that we have ever seen paralysis of a nerve with a dissecting aneurysm. In dissecting aortic aneurysm the aneurysm itself is not particularly large. It is not as a rule a bulbous affair, such as is present in the ordinary syphilitic or arteriosclerotic aneurysm. Occasionally one finds a small hematoma but certainly nothing so large as to affect or infiltrate a nerve. I think that is a good point.

DR. J. H. MEANS: Does a Horner's syndrome occur in aneurysm?

DR. CASTLEMAN: It may be present with a syphilitic aneurysm but not with a dissecting aneurysm.

CASE 31062

PRESENTATION OF CASE

A nineteen-month-old infant was brought to the hospital because of respiratory distress of four and a half hours' duration.

The patient had had a mild cold with no constitutional symptoms for two days. Four and a half hours before admission she developed respiratory distress. This steadily progressed to such an extent that she was brought to the hospital.

Physical examination showed a well-developed, well-nourished, cyanotic infant in acute respiratory distress, gasping for breath. Suprasternal and abdominal retractions were seen with every respiration. The voice was not hoarse. The lungs were clear except for a few coarse and some musical rales audible throughout. The throat was brilliant red. The epiglottis was red and edematous. Examination was otherwise negative.

The temperature was 100°F. (the child had had aspirin); the pulse and respirations were not recorded.

The white-cell count was 25,000. X-ray film of the chest showed a mottled increase in the density of both lower lung fields. The stomach was slightly dilated.

About an hour after admission a 4-mm. bronch scope was passed down to the trachea with extreme difficulty; the entire mucosa was red. A tracheotomy was attempted, but the patient died about one minute before the tube was inserted.

DIFFERENTIAL DIAGNOSIS

DR. ERNA ANDERSON: We have a story of infant with acute infection running such a fulminating course that four and a half hours after the onset of symptoms there was extreme respiratory distress with retractions, cyanosis and gasping respirations. Two conditions are brought to mind that might cause this sequence of events, namely, interstitial pneumonia and laryngotracheobronchitis.

Interstitial pneumonia is an infection frequently seen in infants one year of age or younger, but not infrequently seen in this age group. It is characterized by sudden onset of rapidly increasing distress, with dilatation of the alae nasi and retractions, both suprasternal and subdiaphragmatic. The temperature is variable; the fever may be low, or the temperature may be elevated to 102 or 103°F. The respirations are rapid and shallow. The chest is held in an inspiratory position, but the excursions are limited. On physical examination, rales are heard everywhere. The signs are somewhat generalized. This is a condition in which the interstitial tissue of the lungs is involved, being characterized by patchy areas of atelectasis and emphysema. The signs are not constant. The white-cell count may be normal or slightly elevated. A count of 25,000 is rather high.

The other condition, laryngotracheobronchitis, covers a variety of infections. The most frequent is ordinary mother's croup: this occurs usually at night after the child who has gone to bed feeling apparently well awakens with a hoarse barking cough and may show some evidence of respiratory distress. This disease is generally mild; the symptoms usually subside the following day but may recur again at night. There may or may not be an elevation of temperature.

A severer form of this type of infection is the laryngotracheobronchitis characterized by subglottic edema. In this, again, the onset may be sudden. In general the course is less fulminating than that mentioned in the present case, and the child may be in the hospital for a period of hours before the wisdom of tracheotomy is determined. The temperature may or may not be elevated but is usually about 102 or 103°F. The white-cell count may be normal or slightly elevated. Again, I believe that a count of 25,000 is a little high for that type of laryngotracheobronchitis. It occurs in the age group between one and two years, there is usually no dilatation of the alae nasi, and the child is almost always hoarse.

A third type of infection is characterized by edema and swelling of the epiglottis. This is really an epiglottitis rather than a laryngotracheobronchitis. It is usually seen in children over two years of age, but Sinclair,* reporting his experience at the New Haven Hospital, mentions that it may occur in children as young as four and a half months. The onset is characteristic, with sudden symptoms that progress to a point where tracheotomy is necessary for relief of respiratory distress from four to twelve hours after the onset. There is a peculiar gasping type of respiration, with implication of the accessory muscles of expiration, as well as sub-sternal and abdominal retractions. Dilatation of the alae nasi is usually not seen. The chief complaint is sore throat and dysphagia. Probably this child was too young to make such complaints. Since the infection usually occurs in the epiglottis, above the larynx, hoarseness may not be present since the vocal cords may not be involved. There is usually fever of an extreme degree, 103 to 105°F., and marked leukocytosis, which ranges from 15,000 to 40,000. The children are extremely prostrated and show evidence of overwhelming infection, and in severe cases there may be an associated pneumonia.

In the information we have it has not been mentioned whether or not there was dilatation of the alae nasi. I wonder if we can find out about that.

DR. GERTRUD REYERSBACH: There was dilatation of alae nasi.

DR. ANDERSON: That means that there was extreme respiratory distress, probably pneumonic

rather than tracheal. May we look at the x-ray films?

DR. BENJAMIN CASTLEMAN: There is no radiologist here.

DR. ALLAN M. BUTLER: The report states: "There is definite increase in density in both lower lung fields. The density is mottled in appearance and possibly represents an aspirated pneumonia. The stomach appears to be slightly dilated."

DR. ANDERSON: There is a hazy increase in the markings, as well as the patchy areas of increased density that are mentioned. I was particularly interested to see if there was any evidence of emphysema. It is not mentioned in the report, nor does it appear so to me in the films. The lung fields are not overly clear, and the intercostal interspaces do not seem particularly widened. The position of the diaphragm is relatively normal rather than depressed as one would expect with emphysema. So I think that we can say there was probably no emphysema. The appearance of the x-ray films is not characteristic of interstitial pneumonia. Although some points favor such a diagnosis, the facts that the throat was brilliantly red and the epiglottis red and edematous make me think that this probably falls into the group of cases in which the infection is in the tracheal tree.

It is, of course, of great practical importance to differentiate interstitial pneumonia and laryngotracheobronchitis. In the former condition the obstruction is in the finer radicles and tracheotomy does not help the symptoms, whereas with subglottic or epiglottic obstruction, improvement of the airway below the larynx relieves the respiratory distress. Apparently the service thought that a tracheotomy would be helpful.

Acute epiglottitis is an infectious disease caused by one agent, *Haemophilus influenzae*, and in the reported cases there has always been an associated bacteremia. In spite of the fact that this child was somewhat young, she probably had that disease. It seems likely that the immediate cause of death was laryngospasm, with failure of respiration due to the obstruction. The explanation for this is unsatisfactory. It is assumed to be on a reflex basis. We know clinically that children with laryngeal obstruction are particularly susceptible to laryngospasm, and we hesitate to perform certain procedures without arrangements for immediate tracheotomy at hand. This applies to a digital puncture for obtaining a blood count, to venous puncture for obtaining blood cultures and to swabbing of the nose and throat for culture; it even extends to precautions that should be taken in examination of the pharynx, in which case it is better to use a finger rather than a tongue stick.

I believe that this child had acute epiglottitis, probably due to *H. influenzae*, with associated bacteremia and bronchopneumonia.

DR. BUTLER: I should like to say that this is an

*Sinclair, S. F. *Haemophilus influenzae* type B in acute laryngitis with bacteremia. *J. A. M. A.* 117:170-173, 1941

phrenic nerve. The part of the upper lobe not replaced by the tumor was collapsed.

The tumor involved the bronchus to the left upper lobe and proved to be an oat-cell type of carcinoma, which is prone to surround and invade the bronchial walls with only slight intraluminal tumor, which was true here. As Dr. Aub also predicted, the vertebral spine was practically replaced by tumor and showed a great deal of osteoblastic proliferation and fibrosis, which accounted for the elevated phosphatase.

There were metastases to the adrenal and thyroid glands. The brain showed no evidence of metastasis grossly. There was a hemorrhagic lesion in the left parietal lobe, which I do not suppose accounted for the symptoms. The microscopic sections have not been finished, but grossly it did not look like a metastasis.

DR. AUB: I suppose that the hemorrhage was on a hypertensive basis.

DR. CASTLEMAN: He did have a large heart of the hypertensive type.

DR. CHAPMAN: I want to pay tribute to Dr. Aub for his astute interpretation of the findings, which led to the correct diagnosis. I learned three things from this case that were clinically important. The first is that the nerve paralyses were not caused by a dissecting aneurysm but by the cancer. The second point, which Dr. Aub brought out in interpreting the history, is that the pain was too dragged out and too long to be the pain of a dissecting aneurysm. Dr. Castleman called that to my attention when the case was autopsied. The third point is that the clinical impression should outweigh conflicting x-ray evidence that later comes into the picture.

I started out with a diagnosis of cancer of the upper lobe with obstruction to the bronchus but ended up with a diagnosis of aneurysm. I changed my opinion because when this man was fluoroscoped they said that it was an aneurysm. The appointment for a bronchoscopy was therefore canceled and a definite diagnosis of aneurysm was made. Then the patient was fluoroscoped by Dr. Schulz, who thought that the lesion was cancer; his reasons were that, although he could not differentiate the mediastinal mass, the nerve paralysis, the paralysis of the diaphragm and the separation of the lobe were strongly in favor of cancer of the lung root.

DR. CASTLEMAN: I do not believe that we have ever seen paralysis of a nerve with a dissecting aneurysm. In dissecting aortic aneurysm the aneurysm itself is not particularly large. It is not as a rule a bulbous affair, such as is present in the ordinary syphilitic or arteriosclerotic aneurysm. Occasionally one finds a small hematoma but certainly nothing so large as to affect or infiltrate a nerve. I think that is a good point.

DR. J. H. MEANS: Does a Horner's syndrome occur in aneurysm?

DR. CASTLEMAN: It may be present with a syphilitic aneurysm but not with a dissecting aneurysm.

CASE 31062

PRESENTATION OF CASE

A nineteen-month-old infant was brought to the hospital because of respiratory distress of four and a half hours' duration.

The patient had had a mild cold with no constitutional symptoms for two days. Four and a half hours before admission she developed respiratory distress. This steadily progressed to such an extent that she was brought to the hospital.

Physical examination showed a well-developed, well-nourished, cyanotic infant in acute respiratory distress, gasping for breath. Suprasternal and abdominal retractions were seen with every respiration. The voice was not hoarse. The lungs were clear except for a few coarse and some musical rales audible throughout. The throat was brilliant red. The epiglottis was red and edematous. Examination was otherwise negative.

The temperature was 100°F. (the child had had aspirin); the pulse and respirations were not recorded.

The white-cell count was 25,000. X-ray films of the chest showed a mottled increase in the density of both lower lung fields. The stomach was slightly dilated.

About an hour after admission a 4-mm. bronchoscope was passed down to the trachea with extreme difficulty; the entire mucosa was red. A tracheotomy was attempted, but the patient died about one minute before the tube was inserted.

DIFFERENTIAL DIAGNOSIS

DR. ERNA ANDERSON: We have a story of an infant with acute infection running such a fulminating course that four and a half hours after the onset of symptoms there was extreme respiratory distress with retractions, cyanosis and gasping respirations. Two conditions are brought to mind that might cause this sequence of events, namely: interstitial pneumonia and laryngotracheobronchitis.

Interstitial pneumonia is an infection frequently seen in infants one year of age or younger, but not infrequently seen in this age group. NONESSENTIAL NURSING

IN most departments of social activity it is possible to distinguish between what is essential to the war effort and what is not—especially now that our needs and deficiencies have become so plain. To separate essential from nonessential nursing, however, is a difficult and highly professional matter.

Registered nurses are employed by many physicians for more or less routine office work. Furthermore, there always have been people who indulged themselves unnecessarily in hospital and nursing service; this was an easy thing to do for anyone who could pay his bills, and money is freer now than it ever was before. Luxuries in other fields have been

abolished or rationed, but every practicing physician knows that the abeyance of psychoneurotic complaints that characterized the English blitz of 1940 has no counterpart here.

Some trades and professions have been hit harder than others by the changes of war, but one after another they have managed to meet their national obligations when the squeeze came. The nursing profession is now caught in one of these pinches, and we are beginning to see such headlines as "46 NURSES CARE FOR 1689 WOUNDED." Although most physicians realize that statements of this sort are misleading, since they do not take into account the service given by medical corpsmen, the War Manpower Commission states that 10,000 nurses are urgently needed, and it has been determined on the basis of registered-nurse populations that Massachusetts should supply 969 of these. The Massachusetts Committee for Nurses of the Procurement and Assignment Service has worked hard and long, classifying and reclassifying the women who should be able to meet this crisis. Many who are believed by the committee to be available, however, continue to do what is obviously nonessential nursing. How many registered nurses in doctors' offices are doing work that could not be equally well handled by a medical secretary? How many patients are hospitalized unnecessarily? How many nurses could be freed if their use in private cases were limited to those in which they are really essential?

The first question can be answered only by physicians, and the remedy, if needed, can only be supplied by them. The other questions are being asked by many, and will become more and more widespread as the months of 1945 pass. The Boston City Hospital has begun its answer by insisting that all requests for the assignment of special nurses pass through the hands of the senior visiting physician or surgeon. Other hospitals might follow, or might use other methods. Whole wards for civilian patients might well be closed. Elective surgery might be banned for the duration. For these or for other methods of meeting this emergency the action that will effectively answer the question *must* come from physicians. Every nurse works under a doctor's supervision—and must work with

excellent example of the type of case that demands immediate diagnosis and immediate tracheotomy. The diagnosis apparently was made when this child entered the hospital, since the Emergency Ward note by the pediatric resident states, "The diagnosis is epiglottitis, probably the influenzal type." A nose-and-throat consultant was called, and the child was immediately transferred to the Massachusetts Eye and Ear Infirmary for tracheotomy.

DR. JACOB LERMAN: I should like to ask whether intubation is a practice here rather than tracheotomy.

DR. ANDERSON: I do not believe that intubation is done. At any rate in this case intubation was contraindicated because the obstruction was high and the epiglottitis would still have caused obstruction after intubation.

DR. BUTLER: The real therapy is immediate tracheotomy. The diagnosis can usually be made instantly if the physician thinks of the possibility. The history and the clinical picture are typical. The findings, particularly the large, cherry-red, swollen epiglottis, are practically diagnostic.

DR. ANDERSON: I should like to say that in the reported cases there have been three or four in which recovery has been accomplished without tracheotomy, but all these patients were over five years of age.

DR. CASTLEMAN: Do they give serum or sulfonamide therapy?

DR. ANDERSON: Serum has been given only in the cases in which the infection was overwhelming. Patients in whom tracheotomy is not warranted usually get along well on sulfadiazine.

CLINICAL DIAGNOSES

Acute epiglottitis (*H. influenzae*).
Septicemia (*H. influenzae*).

DR. ANDERSON'S DIAGNOSES

Acute epiglottitis (*H. influenzae*).
Septicemia (*H. influenzae*).
Bronchopneumonia.

ANATOMICAL DIAGNOSES

Acute epiglottitis (*H. influenzae*, Type B).
Septicemia (*H. influenzae*, Type B).
Interstitial pneumonia.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy findings on this child were exactly as Dr. Anderson predicted. There was a marked inflammatory reaction in the epiglottis, which was edematous and fiery red. Microscopic examination showed an extreme degree of inflammation, with polymorphonuclears, practically an abscess, involving the epiglottis. Strangely enough there was relatively little infiltration in the main bronchi, but microscopic sections of the lungs showed a definite infiltration around the smaller bronchioles throughout the lung with lymphocytes, monocytes and a few polymorphonuclears. Therefore, I shall have to make an additional diagnosis of interstitial pneumonia, although it had not progressed sufficiently to give areas of atelectasis and emphysema, such as one usually sees.

A culture of the epiglottis was taken during life but had not been reported by the time the patient died; it yielded *Haemophilus influenzae*, Type B. The spleen was enlarged and showed evidence of acute splenitis.

DR. REYERSBACH: Culture of the heart's blood at autopsy also showed *H. influenzae*?

DR. CASTLEMAN: Yes.

DR. ANDERSON: Did you culture the lungs?

DR. CASTLEMAN: No.

DR. ANDERSON: Sinclair reports that *H. influenzae* was cultured from the lung in some cases that had failed to show pneumonia microscopically, but I suppose that this might be explained on the basis of a positive blood culture.

DR. CASTLEMAN: The pneumonia that one observes in this condition is not the type in which the alveoli are filled with exudate; the infiltration is around the bronchi in the interstitial tissues.

DR. CHESTER M. JONES: The lungs might yield a positive culture in the absence of pneumonic consolidation if the disease process were very early, death occurring before the pneumonia had developed.

DR. ANDERSON: That is what Sinclair attributed the positive cultures to.

WHAT ABOUT HEALTH INSURANCE?*

ROGER I. LEE, M.D.

BOSTON

WORDS may be used to conceal a real meaning, sometimes intentionally and sometimes unintentionally. This is particularly true of those combinations of words that become slogans. This tendency is as old as words themselves, especially if there is a political relation. With the passage of time, a phrase often comes to connote something quite different from the actual meaning of the words. For example, the catch phrase "health insurance" really means quite the reverse; it is insurance to be used when one is sick. Now, the popular connotation of the term is the provision of medical care of some sort, whereas most other plans of insurance provide a cash indemnity or benefit. Certainly this is the connotation of life, fire, theft and other types of insurance. This is what the United States Government proposed to do when it offered insurance against enemy damage to property. If a social organization takes out rain insurance for its annual outdoor strawberry festival, in case of rain the organization gets a cash indemnity. Yet the state of Rhode Island's cash sickness-compensation plan is often designated as a health or sickness insurance plan, with the erroneous assumption that it provides either medical care or the money for that care, whereas the plan provides cash when the worker is ill.

One important reason for some of this confusion is doubtless that sickness is not easily defined. The so-called "private" insurance companies have been wrestling with this problem for many years. From the point of view of these companies, death is a definite affair, fire is somewhat less so, theft leads on to troubled ground, and sickness is a real difficulty. In so-called "life insurance," really death insurance, there is rarely doubt about the death of the insured person. To be sure, in rare instances there has been substitution and even the murder of an insured person for the insurance money. Then, too, there is the occasional person who, when he is told by a physician that he cannot survive, promptly takes out as large an insurance on his life as he can carry. But these cases are unusual, and the insurance com-

panies are constantly putting increased safeguards against such practices.

In the less well-defined forms of insurance, one finds that the insurance companies have had to develop elaborate safeguards to counteract the cupidity and venality of some persons. It takes years to develop these safeguards. For example, the situation of automobile liability insurance is still confused and unsatisfactory in many ways. If and when automobile insurance becomes reasonably satisfactory with increased experience, there will be airplane insurance to be grappled with.

It has taken years to bring a semblance of order out of the workmen's compensation laws and regulations. There are complicated problems, some of which involve the relations of insurance-company doctors with private physicians, as well as the rights of the workingman to his freedom of choice of a physician. Although progress has been made, I believe that no one would claim that the situation is perfect or even satisfactory.

We are now in the midst of a war of extraordinary magnitude. So far as I know, no one questions the obligation of the Government to care generously for the soldiers who have suffered in the defense of their country. Most of us, I think, are prepared to give our soldiers the benefit of any doubt, so that any sifting device does not eliminate the worthy soldiers, even if some perhaps unworthy persons slide through. But even Congress seems confused concerning how far this insurance goes and what the distinction is between insurance against risks of war in the armed forces and so-called "security," however this may be defined, for soldiers and war workers at home. Certainly a grateful government must treat the disabled veterans liberally. If the experiences after other wars are any indicators, however, there will be many problems and many difficulties, and not all of them will be solved to the satisfaction of those concerned.

Some of these difficulties and problems will stem from misunderstandings and from differences in interpretation of the wording of some of the laws and of some of the regulations and directives. Others will arise directly from a lack of agreement about

*An address delivered at a meeting of the Suffolk District Medical Society, Boston, November 18, 1944.

his tacit approval, not only of her knowledge and skill but also of her very employment.

When the questions reach the ears of the public, the answers will have to be those that the public dictates. The doctors should begin to frame answers that are not equivocal. Until the war is over, physicians should *not* employ nurses in their offices if the work can be done by others, civilians should *not* go to hospitals simply because they can have their bills paid, and private nursing care should *not* be permitted unless the patients are critically ill. These are the answers that the public should and will demand.

CANNED HEALTH BROADCASTS

TRUE to the concept that health is a public commodity and that its promotion and preservation should be under the stewardship of the medical profession, the Bureau of Health Education of the American Medical Association offers a new public-address service to state and local medical societies. It has long been a function of the bureau to furnish scripts to be delivered as speeches by local physicians or to be used as rewrite material, but the supply of available local speechmakers is running short. The doctors, interested as they may be in education of the laity, have been forced to streamline their activities; the care of sickness has become a more pressing problem than instruction in the preservation of health.

The new service of the bureau consists, up to the present time, of four series of electrically transcribed radio broadcasts for use in broadcasting to the public and one series for use in connection with health teaching in elementary schools. Complete sets of the records for public broadcasting are available to medical societies as a free loan service, the cost being only that of shipping; the "Health Heroes" set for school use is offered for sale only, at a cost of \$25 per set of twelve programs. In order that this set can be used, the school must have a broadcasting system or a portable record player, or arrangements must be made with a local radio station.

It is reassuring, in these days of social and political unrest, when no one knows what the future may hold for any of us, to realize that our youthful parent

society stands squarely behind a policy of public information. It is further to be expected that when a sound system of medical socialization is presented organized medicine will back that, also, with a right good will.

NOTICES

TUFTS MEDICAL ALUMNI LECTURE

The annual alumni lecture will be given at Tufts College Medical School on Wednesday, February 28, at 4 p.m. Dr. James W. Manary will speak on the subject "The Roads—New and Old."

Physicians and students are cordially invited to attend.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Wednesday, February 21, at 8:15 p.m. There will be a symposium on recent advances in endocrinology.

PROGRAM

Thiouracil in Thyrotoxicosis. Dr. E. B. Astwood.
Gynecologic Endocrinology. Dr. George Van S. Smith.
Pediatric Endocrinology. Dr. Richard Wagner.

NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting of the New England Roentgen Ray Society will be held at the Harvard Club of Boston on Friday, February 16. There will be an x-ray conference at 4:30 p.m. At 8:00 p.m., Dr. Henry L. Jaffe will speak on the subject "Osteoid Osteoma."

HEALTH-OFFICER FELLOWSHIPS

The Commonwealth Fund, of New York City, has recently announced the provision of six fellowships for the training of health officers. All applicants must possess a medical degree, have had at least one year's internship and have shown ability together with interest in and aptitude for public health, men who have had at least a few months' experience in actual public-health work being preferred. Applicants without any experience in public health may have exceptional ability, and if awarded a fellowship, will be provided a full calendar year so that they may have opportunity for some field training either before or after the course of study. Applicants who have not attended a school of public health will be preferred, and the fellowships will be awarded for one school year, except as indicated above. Applicants who have attended a school of public health for one year will be considered for a second year, for the doctorate provided there are available fellowships. The stipends will be \$175 to \$200 a month for single men and \$200 to \$250 a month for married men, depending on circumstances, plus tuition and travel from home to school and return.

Application blanks and further information may be obtained from the Division of Public Health, Commonwealth Fund, 41 East 57th Street, New York 22, New York.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 15

FRIDAY, FEBRUARY 16

*9 00-10 00 a.m. Dwarfism Dr. Nathan Talbot. Joseph H. Pratt Diagnostic Hospital.

10 50 a.m. Use of Antibiotics in Dermatology Dr. G. E. Mori (Postgraduate clinic in dermatology and syphilology) Amp theater, Mallory Building, Boston City Hospital.

SATURDAY, FEBRUARY 17

*10 00 a.m.-12 00 m. Medical staff rounds. Peter Bent Brigham Hospital

(Notices continued on page xix)

the meaning of words and the inability to define precisely certain terms, such as "wound," "injury" and "sickness." The addition of the phrase "service-incurred disabilities" adds to the confusion. I recount these facts without comment, certainly no adverse comment, because it seems to me to help to clarify thinking on the whole insurance situation that is developing before us.

The inability to define illness precisely has always been a bugaboo of the medical profession. Even as medical science has progressed in the precision of diagnosis, there is always a shifting no-diagnosis land. In some cases it seems right in front of one; again, it seems just on the horizon. Doubtless it furnishes sustenance to quackery and charlatanism.

The story is told of Dr. Henry J. Bigelow at the Massachusetts General Hospital, according to which a desperately ill patient, who had been treated by an irregular practitioner for "rheumatism of the liver," was admitted to the hospital. At the autopsy, on the insistence of Dr. Bigelow, the physician appeared. The liver was quite normal. Dr. Bigelow turned to the quack and made some scornful remarks. The quack replied: "Yes, Dr. Bigelow, the liver is normal. I cured that liver. I wish you had done as well with the malady that killed the patient." The medical profession points to the fantastic accounts of cures of various cults as evidence not usually of mistaken diagnoses on the part of doctors, but rather of the mistaken and often honest beliefs on the part of patients that they were really sick. Such convictions are sometimes dis-

lodged by an emotional impact that is part of the stock in trade of the cultists.

The medical profession is therefore not surprised at the difficulties arising from the inability to define sickness in the area of insurance. Experience has taught that, whereas statistics may show a definite rate of sickness, under conditions of insurance this rate is increased, perhaps doubled or trebled. Furthermore, the explanation does not entirely lie in the fact that medical service without the fee-for-visit arrangement will reveal otherwise neglected sickness. Nor does the explanation depend entirely on the desire to get a return on money expended for insurance protection. It is necessary to study and digest these actuarial figures. The same difficulty is encountered in every army that supplies medical service for all and has no fee-for-service arrangement, particularly in the case of troops who are undergoing training that is vigorous, with the quality of leadership leaving something to be desired. We call it harsh orders, ill-advised punishments and scanty morale. Low morale occurs everywhere at times.

Perhaps the psychiatrist and social worker have ages, the doctors have recognized all this and more. sympathy and firmness are helpful. Through the therapeutic measures in or out of the Army, but and "tough" medical consideration are not effective in obstetrics, in acute illnesses like pneumonia, in the hospitalization of fractures and in surgical operations for acute conditions. traps with many complaints.

But the insurance principle has in general worked well in a good many areas. Consequently, there was inevitably further trial of this principle in sickness. The large private insurance companies have experimented extensively with it. Despite substantial progress, I believe it to be true that the inherent difficulties and problems have not been solved and that accurate and reliable actuarial figures are still lacking. One substantial obstacle has been the lack of an explicit and usable definition of sickness. Certain applications of the insurance principle for sickness that have been tried and tested have had some success, even if not perfect success. If the insurance principle is applied to a homogeneous group like the students in a school, college or university, it is apt to work well, although by no means perfectly and not always smoothly. In a homogeneous unit, such as a lumber camp or a mining community, the principle seems to work on the whole fairly well, but it is impossible to generalize because local conditions defy all generalities. Then, too, any lack of homogeneity is always disturbing. For example, the inclusion of families in the operation of the plan makes for difficulties. Again, it is one thing when there is no medical competition nearby, and another thing if there is an existing community with other industries and other forms of medical care. Certain communities with a fairly common interest, however, are being well looked after in insurance plan suited to the particular circumstances.

the meaning of words and the inability to define precisely certain terms, such as "wound," "injury" and "sickness." The addition of the phrase "service-incurred disabilities" adds to the confusion. I recount these facts without comment, certainly no adverse comment, because it seems to me to help to clarify thinking on the whole insurance situation that is developing before us.

The inability to define illness precisely has always been a bugaboo of the medical profession. Even as medical science has progressed in the precision of diagnosis, there is always a shifting no-diagnosis land. In some cases it seems right in front of one; again, it seems just on the horizon. Doubtless it furnishes sustenance to quackery and charlatanism. The story is told of Dr. Henry J. Bigelow at the Massachusetts General Hospital, according to which a desperately ill patient, who had been treated by an irregular practitioner for "rheumatism of the liver," was admitted to the hospital. At the autopsy, on the insistence of Dr. Bigelow, the physician appeared. The liver was quite normal. Dr. Bigelow turned to the quack and made some scornful remarks. The quack replied: "Yes, Dr. Bigelow, the liver is normal. I cured that liver. I wish you had done as well with the malady that killed the patient." The medical profession points to the fantastic accounts of cures of various cults as evidence not usually of mistaken diagnoses on the part of doctors, but rather of the mistaken and often honest beliefs on the part of patients that they were really sick. Such convictions are sometimes dislodged by an emotional impact that is part of the stock in trade of the cultists.

The medical profession is therefore not surprised at the difficulties arising from the inability to define sickness in the area of insurance. Experience has taught that, whereas statistics may show a definite rate of sickness, under conditions of insurance this rate is increased, perhaps doubled or trebled. Furthermore, the explanation does not entirely lie in the fact that medical service without the fee-for-visit arrangement will reveal otherwise neglected sickness. Nor does the explanation depend entirely on the desire to get a return on money expended for insurance protection. It is necessary to study and digest these actuarial figures. The same difficulty is encountered in every army that supplies medical service for all and has no fee-for-service arrangement, particularly in the case of troops who are undergoing training that is vigorous, with the quality of leadership leaving something to be desired. We call it morale. Low morale occurs everywhere at times. Harsh orders, ill-advised punishments and scanty and "tough" medical consideration are not effective therapeutic measures in or out of the Army, but sympathy and firmness are helpful. Through the ages, the doctors have recognized all this and more. Perhaps the psychiatrist and social worker have given it a new emphasis. But it is as new or as old

as the Golden Rule. Indeed, its application to insurance is not new. At one time, lodge doctors were common. The medical benefits were bait to attract members, and perhaps also a red herring across the trail of masculine social gatherings for the deception of the wife. Young doctors and unsuccessful ones took the jobs of lodge doctors as a possible introduction to practice. They were not paid much, and as a rule they rendered very little and very unsatisfactory service. Indeed, it was sometimes a degradation to depend exclusively on the lodge doctor, to "die to him," as we say in New England. But he was supposed to be better than nothing for the down-and-outers and the chronic medical tramps with many complaints.

But the insurance principle has in general worked well in a good many areas. Consequently, there was inevitably further trial of this principle in sickness. The large private insurance companies have experimented extensively with it. Despite substantial progress, I believe it to be true that the inherent difficulties and problems have not been solved and that accurate and reliable actuarial figures are still lacking. One substantial obstacle has been the lack of an explicit and usable definition of sickness. Certain applications of the insurance principle for sickness that have been tried and tested have had some success, even if not perfect success. If the insurance principle is applied to a homogeneous group like the students in a school, college or university, it is apt to work well, although by no means perfectly and not always smoothly. In a homogeneous unit, such as a lumber camp or a mining community, the principle seems to work on the whole fairly well, but it is impossible to generalize because local conditions defy all generalities. Then, too, any lack of homogeneity is always disturbing. For example, the inclusion of families in the operation of the plan makes for difficulties. Again, it is one thing when there is no medical competition nearby, and another thing if there is an existing community with other industries and other forms of medical care. Certain communities with a fairly common interest, however, are being well looked after medically by homogeneous groups of doctors on an insurance plan suited to the particular circumstances.

As a further illustration of what I mean by the homogeneous factor in the insurance principle and the difficulties in the lack of an adequate definition of sickness, I shall cite the example of the Blue Cross. Now, the Blue Cross concerns itself only with hospitalization. It excludes chronic illness and certain diseases. It pays or helps to pay the hospital rates in obstetrics, in acute illnesses like pneumonia, in the hospitalization of fractures and in surgical operations for acute conditions. It is popular because it helps pay for the acute catastrophic emergencies. It does not pay doctors' bills — sometimes, I fear, to the surprise and disappointment of the subscribers. It does not pay for sickness outside the

hospital, — that is, at home, — and it does not pay or help pay bills in hospitals that it does not recognize. The Blue Cross represents an insurance principle that sharply defines sickness — the patient must be hospitalized in an approved hospital with an acute and recognized sickness. It recognizes the homogeneous factor for the same reasons. Even though generally successful, the Blue Cross has not solved all the problems even within its own limited field.

Experimentation has gone even farther. Already various medical groups, notably some of the county medical societies and several of the state medical societies, have sponsored plans for the introduction of medical care in communities, districts, counties and states. These experiments have had many obstacles to overcome and have met with many vicissitudes. As a result of experience at the present time, most plans begin by limiting themselves to obstetrics and surgery — that is to say, sickness that can be more or less explicitly defined. Some of these plans show considerable promise. In any event, they seem to be based on a firmer foundation than the scores of earlier plans under all kinds of auspices that have passed into oblivion. Furthermore, these newer plans, in their pioneering work, test out by trial and error their feasibility and the desires of the public, and they are producing valuable data, including actuarial figures. Some of these plans by affiliation with the Blue Cross are able to furnish complete coverage of hospital and doctors' bills. But, as I have said before, all the problems are not solved. Obviously, a Blue Cross subscriber may prefer hospital residence for a minor operation or a minor illness that might be cared for at home, but he is a subscriber and is entitled to consideration. The hospitals may be overtaxed by this load; indeed, a new type of hospital or hospital wing or ward may be needed. The present "super" hospitals may be too expensive to operate for minor classes of medical illness or of surgery. As you all know, here in this state the Massachusetts Medical Society has fostered and sponsored a plan for state-wide prepayment insurance for low-income groups on a nonprofit basis. Dr. James C. McCann, of Worcester, has borne the heavy burden of inaugurating this plan, called the Blue Shield. The Blue Cross has made generous contribution not only of experience and advice but also of its personnel and organization. A sound and substantial beginning has been made. So far, the Blue Shield accepts only surgical and obstetric cases. To be sure, these are the large catastrophic financial items, if one permits the use of the word "catastrophic" as applied to obstetrics. It is certainly the intent to progress farther into the realm of sickness when experience warrants such a move. Of course, there will be difficulties. Once again the specter of definition raises problems. What is the ceiling — to employ the modern jargon — of low-income groups? And

incidentally what is the floor? In any event, the doctors are proceeding with their experiment. They have put real money — their own money, too — into the experiment and promise a good try at a possible solution. The members of the medical profession in some other states, in some counties, in some communities and in some areas are also experimenting with similar plans, with varying success. Some of the earlier plans under medical auspices based rather on sentiment and enthusiasm than on actuarial figures and cautious experimentation have passed into oblivion, but these should be remembered as revealing many pitfalls not readily apparent to the unwary.

One of the products of these activities — or perhaps one of the many stimulating forces — has been the advocacy in some quarters of a universal health-insurance plan on a nationwide scope. There is nothing new about compulsory health insurance, so called. It has been agitated in this country for fifty years at least. In the 1880's Germany adopted a plan of sickness insurance that was carefully studied and that seemed to work well for the Germans, particularly in the case of tuberculosis. The rather sudden drop in the incidence of tuberculosis in all countries irrespective of health insurance and the ability of this country largely to meet this problem on a state or even a smaller unit level seemingly discouraged enthusiasm for such a plan here.

The adoption of compulsory health insurance in the British Isles thirty years ago, however renewed the discussion. Other European countries before and since have adopted varying schemes of compulsory sickness insurance, usually on a nationwide level. The course of compulsory health insurance in Britain has been followed with great interest in this country. Contrary to the expectations and even the promise of its proponents, it has been concerned with sickness and not with health. The public-health activities have been minimized rather than emphasized. The death rate has not been lowered so rapidly as that of the United States. There has been much discussion and much acrimony on both sides of the question and on both sides of the Atlantic. The operation of the British act has not been free from politics; it has not improved medical practice and indeed has been a good deal of a deterrent to the public-health movement. There have been the usual difficulties of all insurance plans. At the present time, changes in the British act are contemplated and are being discussed. The medical profession of Great Britain does not find the act satisfactory but is reluctant to encourage drastic changes that it fears would eventually result in more governmental and political control. It pleads for cautious experimentation and for action only after study of the actuarial data, and for freedom from political manipulations. The medical profession in Great Britain wants clarification of governmental activities in respect to poverty and medical service.

the meaning of words and the inability to define precisely certain terms, such as "wound," "injury" and "sickness." The addition of the phrase "service-incurred disabilities" adds to the confusion. I recount these facts without comment, certainly no adverse comment, because it seems to me to help to clarify thinking on the whole insurance situation that is developing before us.

The inability to define illness precisely has always been a bugaboo of the medical profession. Even as medical science has progressed in the precision of diagnosis, there is always a shifting no-diagnosis land. In some cases it seems right in front of one; again, it seems just on the horizon. Doubtless it furnishes sustenance to quackery and charlatanism. The story is told of Dr. Henry J. Bigelow at the Massachusetts General Hospital, according to which a desperately ill patient, who had been treated by an irregular practitioner for "rheumatism of the liver," was admitted to the hospital. At the autopsy, on the insistence of Dr. Bigelow, the physician appeared. The liver was quite normal. Dr. Bigelow turned to the quack and made some scornful remarks. Indeed, it was sometimes a degradation to depend exclusively on the lodge doctor, to "die to him," as we say in New England. But he was supposed to be better than nothing for the down-and-outers and the chronic medical tramps with many complaints.

But the insurance principle has in general worked well in a good many areas. Consequently, there was inevitably further trial of this principle in sickness. The large private insurance companies have experimented extensively with it. Despite substantial progress, I believe it to be true that the inherent difficulties and problems have not been solved and that accurate and reliable actuarial figures are still lacking. One substantial obstacle has been the lack of an explicit and usable definition of sickness. Certain applications of the insurance principle for sickness that have been tried and tested have had some success, even if not perfect success. If the insurance principle is applied to a homogeneous group like the students in a school, college or university, it is apt to work well, although by no means perfectly and not always smoothly. In a homogeneous unit, such as a lumber camp or a mining community, the principle seems to work on the whole fairly well, but it is impossible to generalize because local conditions defy all generalities. Then, too, any lack of homogeneity is always disturbing. For example, the inclusion of families in the operation of the plan makes for difficulties. Again, it is one thing when there is no medical competition nearby, and another thing if there is an existing community with other industries and other forms of medical care. Certain communities with a fairly common interest, however, are being well looked after medically by homogeneous groups of doctors on an insurance plan suited to the particular circumstances.

As a further illustration of what I mean by the homogeneous factor in the insurance principle and the difficulties in the lack of an adequate definition of sickness, I shall cite the example of the Blue Cross. Now, the Blue Cross concerns itself only with hospitalization. It excludes chronic illness and certain diseases. It pays or helps to pay the hospital rates in obstetrics, in acute illnesses like pneumonia, in the hospitalization of fractures and in surgical operations for acute conditions. It is popular because it helps pay for the acute catastrophic emergencies. It does not pay doctors' bills — sometimes, I fear, to the surprise and disappointment of the subscribers. It does not pay for sickness outside the

hospital, — that is, at home, — and it does not pay or help pay bills in hospitals that it does not recognize. The Blue Cross represents an insurance principle that sharply defines sickness — the patient must be hospitalized in an approved hospital with an acute and recognized sickness. It recognizes the homogeneous factor for the same reasons. Even though generally successful, the Blue Cross has not solved all the problems even within its own limited field.

Experimentation has gone even farther. Already various medical groups, notably some of the county medical societies and several of the state medical societies, have sponsored plans for the introduction of medical care in communities, districts, counties and states. These experiments have had many obstacles to overcome and have met with many vicissitudes. It pleads for cautious experimentation and for action only after study of the actuarial data, and for freedom from political manipulations. The medical profession in Great Britain wants clarification of governmental activities in respect to poverty and medical service.

In other words, the doctors object to the government's giving medical care as a dole to the poor, instead of providing them with the necessities of life — shelter, food, fuel, clothing and so forth. It is necessary, they claim, to separate poverty and the measures used to alleviate poverty from sickness and the measures used to alleviate sickness. Doubtless there is a connection between poverty and illness. One may well be the cause of the other, but poverty is not always the cause of illness. And certainly financial security does not ensure freedom from disease or freedom from worry.

Sir William Beveridge, the well-known British economist, and his plan decidedly stimulated the discussion. If I understand the plan correctly, it is an attempt to show how the insurance principles may be used, primarily against poverty and incidentally against unemployment, old age, the bringing up of children and so forth, including illness. Sir William recognizes five giants of evil — want, disease, ignorance, squalor and idleness. He claims that want or poverty is probably the easiest to attack. His plan is focused primarily on poverty and incidentally on sickness. He does not himself seem to have any opinion about its workability. Indeed, in a lecture in London some years ago he declared that it was not the business of the professional economist to develop legislation to any end. I believe, however, that Sir William has recently been elected to Parliament, so he may have changed his mind. Then, being an Englishman, he is a bit hazy on the role of hospitals in illness. One of the proponents of the federal compulsory-insurance law in the United States wrote to me that it did seem that Sir William was rather vague on the subject of hospitals. In the United States, of course, the hospital is on the front line in the battle against illness. In any case, it is difficult or impossible to transfer the experience of one country to another. Even in Great Britain, the Compulsory Insurance Act in a number of respects is different in Scotland from what it is in England, although both countries are on the same relatively small island. The people of England and Scotland together are decidedly more homogeneous than the people in this vast country. The British have no Negro problem, for example. They have an Indian problem, to be sure, but not in the British Isles. Medical education in Great Britain is vastly different from that in the United States. The whole system of medical practice is different. The British still talk of nursing homes instead of private hospitals. Their nursing service is generally considered to be inadequate. Of course, I should hasten to say that the best of medical science and of medical practice in the British Isles is as good as that anywhere in the world, but the top-flight men are relatively few. In the United States, many of the rank and file of the profession are close to the top, which is certainly not the case in England.

Certainly at one time during the last thirty years the medical profession and the British Medical Association seemingly accepted the plan of compulsory health insurance; perhaps passive resignation to the act is more accurate phraseology. But more recently vigorous objection is being voiced. A Scottish physician entirely unconsciously illustrated some of the drawbacks and weaknesses of the act when he assured me that he liked the plan. The reason he gave was that after years of hard work the doctor had something that he could sell when and if he was minded to retire. Naturally, I asked him if a physician could turn over his panel patients in that fashion. Of course, said he, if one stood in well with the administrator, who ordinarily is not a doctor. I did not think it was appropriate to ask how one stood in well with the administrator, but did venture to ask about the application of the principle of freedom of choice on the part of the panel patients. He put me in my place emphatically and profanely for my visionary foolishness in regard to this, and in regard to my next query which concerned what would happen if the purchaser proved to be incompetent.

The Scottish physician was a man of some importance in his community and in the profession. His remarks were sadly substantiated by other physicians, who, as doctors are wont to do, retailed their own pet grievances. A common grievance was that the administrator was often arbitrary in refusing approval of expensive drugs. As we all know, some doctors prescribe preparations of drugs that are expensive when inexpensive preparations may be just as good or even identical. I got the impression, however, that there was a substantial reason for the grievance.

The big frogs in the medical puddle — that is, consultants on Harley and Wimpole streets in London and their prototypes in smaller centers — find that they derive a considerable consultation practice rather directly from this panel system. The panel physician sees the patients in his surgery, but if the patient desires or needs even a routine examination, too often he has to get it at his own expense from the consultant.

My best guess is that, by and large, the doctors in Great Britain benefit financially by this system. It is to be noted that the system was not inaugurated by the doctors. From it has developed what seems to be a sorry state of affairs for the patient and for medical standards of practice.

I have dwelt on the British experience with compulsory insurance because it is so much in the discussion, as well as because it shows clearly some of the fundamental difficulties in a nationwide plan. On the state level or lower, the same and additional difficulties have been discovered in this country. I believe that if the whole subject of compulsory insurance for sickness were better understood, possibly more profitable progress might be made. It

The big frogs in the medical puddle — that is, consultants on Harley and Wimpole streets in London and their prototypes in smaller centers — find that they derive a considerable consultation practice rather directly from this panel system. The panel physician sees the patients in his surgery, but if the patient desires or needs even a routine examination, too often he has to get it at his own expense from the consultant.

My best guess is that, by and large, the doctors in Great Britain benefit financially by this system. It is to be noted that the system was not inaugurated by the doctors. From it has developed what seems to be a sorry state of affairs for the patient and for medical standards of practice.

I have dwelt on the British experience with compulsory insurance because it is so much in the discussion, as well as because it shows clearly some of the fundamental difficulties in a nationwide plan. On the state level or lower, the same and additional difficulties have been discovered in this country. I believe that if the whole subject of compulsory insurance for sickness were better understood, possibly more profitable progress might be made. It

is painful to report that many doctors have little basic information on the topic. Too often some doctors express very emotionally their prejudices against what they regard as interference with the present system of medicine, which beyond doubt is the most effective in the world, but which is far from perfect and which can and should be improved, particularly so far as distribution of medical service is concerned. At times, the doctors are so vehement that they are charged with selfish interest. On the other hand, the average citizen thinks of his own selfish interest. He is, as a rule, interested mainly in good medical care, to be sure, but also at the lowest financial rate. The patient naturally wonders whether the insurance plan will not help his pocket-book. When the discussion becomes acute or acrimonious, the character of medical service gets lost. Thoughtful persons are properly much concerned over the quality of medical service. To me this is the nub of the whole matter, and I believe that this is the view of the substantial proportion of the medical profession. Changes will and must go on in the future. They have in the past. Anyone who thinks back, not thirty years but ten years, is acutely conscious of change. Certainly any doctor active in practice is aware of his own role in the change in medical practice. Otherwise, he would not be active in practice. I say this with the full conviction that the doctor is not sacrosanct and not even master of his own destiny. He is peculiarly a product and a creature of the community. The doctor does not want to dominate or dictate. He could not if he would. He is, however, the expert witness in the case. In the meantime, experimentation must and will continue. It is unthinkable that without careful study of the difficulties as actually encountered any revolutionary change will be adopted. Thinking is needed more than emotional slogans in which words do not mean what they ought to mean.

Personally, I am in favor of a broad, vigorous attack on poverty and want. Old age and unemployment must be faced and provision must be made for them. But mark you this, and to me the difference is vital, a pension is given to the elderly and a cash benefit to the unemployed, but in the case of illness in federal compulsory-insurance plans, medical service, not cash, is to be furnished through the government to the sick. Why this curious distinction, and why not keep separate, so far as possible, poverty and illness? And what if a government undertook not to supply cash to old age or for unemployment but to utilize the same principle as suggested for medical service? Would it be old age homes, or else, or particular jobs for the unemployed, or else? Is the question real or rhetorical, and why?

Poverty and want exist in the United States, even if they are not so horribly conspicuous as in Britain. And in no country does the attempted control of

poverty and want include that social misfit so accurately described by Prime Minister Churchill as the "pub crawler." In America, he is the "bar-room bum."

Since we have the Social Security Act in this country, I see no reason for the exemption of those employed in educational and religious institutions and in hospitals. My personal concern, as I have said before, is the quality of medical service, which must always be rising to higher and higher standards to ensure a healthy and happy people.

Certainly one must appreciate as an illustration the phenomenal growth of private insurance in the United States. There are now more than eighteen thousand industrial firms that are covered, with more than twenty million policyholders. They are covered, in most instances, with hospitalization, a \$10 weekly disability allowance, \$100 to \$150 for surgical fees and an allowance for laboratory and x-ray charges. One medical society is arranging with an insurance company to cover everybody in the county in groups of five or more people.

Given reasonable opportunity, it seems likely that private insurance can do the job better in the United States than can the federal government.

Within the seemingly visible future, the war for freedom will be won. Paradoxically, to win this freedom we have had to sacrifice some of our own freedom. This we have done gladly and cheerfully for the cause. After the cessation of armed hostilities we shall have another freedom to win. We shall be tired; we shall be used to regimentation and to bureaucratic regulation of this and that. But I believe that we shall win back that freedom too. I believe that there is enough intelligence, enough imagination, enough initiative, enough resourcefulness and enough resolute determination to solve in our own American way these problems that I have discussed tonight. I believe that only dull and weary people turn their problems and troubles, with their freedom, over to others, which is in this case the government.

We may or may not like the lesson, but the glorious youth of this country has taught us of the older generation that too often what we thought was parental interest and solicitude was actually to their view paternalism, even if friendly, and at times a form of despotism even if benevolent in design. They want freedom, not paternalism or despotism, and we must give it to them, albeit with a prayer that they do not confuse license and liberty.

Once more I want to state with all the emphasis that I possess that this country needs better medicine. In improving medical service, the problems of better distribution must and will be solved. But let us not forget that we still need better doctors and better medical practice.

264 Beacon Street

THE McMURRAY OSTEOTOMY FOR NONUNITED HIP FRACTURES*

OTTO J. HERMANN, M.D.†

BOSTON

IN OCTOBER, 1939, I¹ reported on a small series of hip reconstructions done for painful, non-united fractures of the femoral neck under the various prevalent standard procedures. These included the Colonna modification² of the Whitman method, the Magnuson modification³ of the Brackett operation, direct bone graft and hip fusion.

On the whole, the percentage of good end results was discouraging, except, perhaps, for those obtained from the hip-fusion method. The temptation to adopt this procedure as the one of general choice was great, but I believed that it should not be done. After reading McMurray's⁴ paper on fractures of the neck of the femur treated by oblique osteotomy, I was eager to try out his method on some painful nonunited hip fractures. At about that time, however, a discouraging talk with two surgeons from across the Atlantic on the ultimate (three-year) end results deflected me temporarily from going ahead with McMurray's osteotomy treatment. Some time later, after thinking over the reports of McMurray⁴ and others of the high percentage of successful end results following such osteotomies, giving a high degree of painless hip function, which was nearly normal in many cases, I began doing the McMurray type of oblique osteotomy in a few selected cases of painful nonunited hip fractures. For two years the following McMurray technic, as described by me¹ in 1939, was used.

The McMurray osteotomy . . . is a bifurcation operation based on the suggestion of Lorenz in which the shaft of the femur is transferred directly under the lower margin of the acetabulum and head of the femur. The chief purpose of this operation is to change a shearing force into a direct one. The following are the steps in this operation:

A 15-cm. incision is made along the lateral side of the upper end of the femur in the trochanteric area. The fracture site is exposed so as to place the osteotomy line accurately. An oblique osteotomy is performed beginning on the outer side of the shaft, generally about the lower end of the greater trochanter and ending above the tip of the lesser trochanter. The upper end of the shaft of the femur is pried and shoved inward until the cut end is under the acetabulum and femoral head. This is followed by repair of the wound. A plaster-of-Paris fixation is used for a period long enough to ensure union at the site of the osteotomy. This fixation of the limb is in the neutral position in very slight abduction in order to prevent the development of knock-knee following removal of the plaster cast. Fixation is maintained generally three and a half to four months. The knee is kept in slight flexion so that the degree of rigidity is decreased.

In September, 1941, I⁵ reported, besides other types, 8 nonunited hip fractures treated by McMurray's procedure. Six of them had progressed, as I thought, long enough to give a fair evaluation of their end results. At that time I wrote:

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 24, 1944.

†Associate in surgery, Harvard Medical School; clinical professor of surgery, Tufts College Medical School; surgeon-in-chief, Bone and Joint Service, Boston City Hospital.

Five of the 6 cases have gone clinically to good end results, and 1 patient, although not an absolute failure, still has to use crutches after six months. . . . In the few cases done by this method at our hospital the following data have been gathered: the patients have plaster-of-Paris spica fixation from eight to fourteen weeks, and hospitalization from ten to about seventeen weeks; they generally leave the hospital using crutches but soon thereafter omit them and use only a cane, with good clinical end results; they still use a cane in going upstairs, limp slightly, but have no local hip pain or tenderness on walking, sitting or lying down; the shortening varies from 2.2 to 2.6 cm.; there is a limited degree of internal, but a good degree of external rotation at the reconstructed hip, and also a good abduction and adduction range; there may be occasional stiffness; the patients can dress themselves in normal fashion, cross their knees and sit for protracted periods with ease and comfort. In short, a good 80 to 85 per cent return to normalcy is usually obtained. . . .

At present the McMurray osteotomy seems adaptable to a greater variety of the painful nonunited femoral-neck fractures than the other methods. The other points in its favor are its simplicity of execution, the production of less surgical shock and, lastly, the fairly high rate of good end results showing a very creditable percentage of return to normalcy.

Since the publication of this report, 11 more such reconstructions have been done at the Boston City Hospital by various surgeons. Two modifications in the technic were added. First, to place the osteotomy line more accurately a Kirschner wire is inserted in the proposed osteotomy line and its position is checked by x-ray, the wire then being used as a guide in doing the actual osteotomy. Second, in several cases the Blount blade plate has been used as a means of internal fixation after the osteotomy has been done. The first modification served to place the osteotomy much more accurately than the ordinary touch method, and the second was a definite improvement in that it was possible to do away with the prolonged plaster-of-Paris spica fixation and bed confinement, and it also prevented the cut end of the distal femoral shaft from slipping or sliding out.

Five of the 8 cases reported in 1941 have been re-examined. In all of them the 1941 end results had been deemed successful. Two patients have developed considerable pain, have lost some of their local hip-motion range, and show an increase in shortening because of some change in position of the distal femoral shaft due to lack of real bony union. Thus, the 1941 rating of the McMurray osteotomy has had to be revised downward.

Of the last 11 patients treated, 2 died soon after the operation, one three days afterward from cerebral thrombosis, and the other within twenty-four hours from cardiac failure. These 11 cases have been summarized as follows:

CASE 1. L. S., a 51-year-old woman, received on 1943, a McMurray osteotomy for a painful nonunion of the right femoral neck in which the pi

Kirschner-wire technic was adopted. A plaster-of-Paris spica fixation was used, with the leg in 20° abduction and in the neutral position, until September 24. The patient was discharged on October 3 on crutches. She discarded them on October 10 and used a cane until December 25. She now limps somewhat but can do her daily routine walking. She can sit with complete comfort for several hours, although the leg stiffens temporarily after 1½ hours of sitting. There is some soreness of the hip at night and during inclement weather. She can go up and down stairs one step at a time using a cane. A recent physical examination revealed a 3-cm. shortening of the right leg. The internal rotation was practically nil and the external rotation 20°. Adduction was limited to 15°, and abduction to 25°. The quadriceps muscle group showed some atrophy. The patient had some difficulty in putting on her stocking and shoe.

Comment. This case does not show an 80 or 85 per cent return to normalcy, but the patient has an almost painlessly functioning hip and can do her routine daily walking and sitting, neither of which was possible before the osteotomy.

CASE 2. J. DeL., a 51-year-old man, received on March 3, 1943, a McMurray oblique osteotomy followed by a Blount internal blade-plate fixation. He left the hospital on crutches on April 6, and the crutches were discarded in July. Since then the patient has used a cane or one crutch. He was non-co-operative, and it was difficult to convince him that daily routine leg exercises and walking were important to his progress. He now does more walking but has recurring pain in the hip when tired. He can, however, sit with comfort and can put on his sock and shoe without much difficulty. The leg presents a 3-cm. shortening with only slight internal rotation. Adduction is limited to 15° and abduction to 30°. Flexion at the thigh is 35°. The patient goes up and down stairs with the aid of the railing or a cane.

Comment. This patient can at least walk and sit with a fair degree of comfort and can dress himself, neither of which was possible previous to the osteotomy. Although there is recurring pain on tiring after long walks, it ceases after a short rest and is thus not so severe and persistent as before the operation.

CASE 3. E. C., a 76-year-old woman, received on September 23, 1942, a McMurray osteotomy for a painful, non-functioning, nonunited fracture of the right hip. A plaster-of-Paris spica fixation was used for 3 months. The patient was discharged on January 8, 1943, using crutches with active weight bearing. She discarded one crutch on February 1, used the other for another month, and has since been using a cane. She had complete relief of pain for 5 months following the operation, but at present has some pain in the hip and knee, which is relieved by acetylsalicylic acid. She does her normal amount of daily walking, goes to the motion pictures and sits for several hours with comfort, does her daily housework and can easily put on her shoe and stocking. She does, however, limp somewhat and still uses a cane. The right leg shows a 3-cm. shortening. There is limited internal rotation at the right hip but 40° of external rotation. Adduction is limited to 15° and abduction to 25°. There is 15° flexion deformity. The patient walks with the right leg in some degree of external rotation.

Comment. This can be considered a fair end result only in that the patient can walk, sit and dress herself with a fair degree of ease and do her daily housework, none of which could be done before the operation.

CASE 4. M. M., a 50-year-old woman, received a McMurray osteotomy on May 20, 1942. A plaster-of-Paris spica was applied for 13 weeks. The patient was discharged on August 17 on crutches, used them until July, 1943, then discarding them for a cane. At present she is doing a moderate amount of walking. She returned to her work as a telephone operator in the summer of 1943. She can sit with comfort. The only pain she has in her hip is of moderate degree and appears — strangely enough — on arising in the morning. The leg presents a 2.5-cm. shortening. Adduction is limited to 20° and abduction to 25°. There is internal rotation of only a few degrees, but external rotation of 45°. There is a flexion deformity of 15°, with further flexion to 90°.

Comment. This patient progressed slowly — owing to her apprehensive attitude — to a reasonably good end result. She

walks well with the aid of a cane, and can sit with ease for protracted periods, as her work attests. She still has difficulty in putting on her shoe and stocking. She could not walk or sit with comfort previous to the operation.

CASE 5. E. W., a 62-year-old woman, received a McMurray oblique osteotomy for painful nonunion of a fracture of the left hip on October 23, 1942. A plaster-of-Paris spica was applied. This operation was done under intravenous Pentothal Sodium anesthesia. The patient showed no unfavorable immediate postoperative reaction, but 3 days later died from cerebral thrombosis.

CASE 6. N. J., a 65-year-old woman, received a McMurray osteotomy on February 12, 1942, after having been treated medically for arteriosclerotic disease. She was considered a fair risk for the osteotomy, but died 24 hours post-operatively from cardiac failure.

Comment. Although the patient in Case 5 appeared to be an excellent operative risk, Case 6 was of the borderline type, preoperative medication being necessary for over a month. It would probably have been better judgment to let this patient remain a wheel-chair invalid.

CASE 7. J. P., a 62-year-old man, received a McMurray osteotomy for the left femur on February 20, 1942. A plaster-of-Paris spica fixation was used for 3 months. The patient was discharged on June 1, using crutches. He is now up and about using a cane. He can walk with comfort, has no hip pain and gets about much better than before. He cannot cross the left knee over the right, but he can put on his sock and shoe. He can go up and down stairs using the banister and a cane. The leg presents a 3-cm. shortening. There is practically no internal rotation at the hip, but there is external rotation of 25°. Adduction is limited to 20° and abduction to 25°. There is a 10° flexion deformity, with further flexion to 70°.

CASE 8. J. McG., a 69-year-old man, received on November 11, 1941, a McMurray osteotomy for a nonunited fracture of the left femoral neck, performed by the preliminary Kirschner-wire technic. A plaster-of-Paris spica fixation was applied until January 16, 1942. Because of some stiffness of the left knee, he was put on balanced traction. On February 11, he started using crutches, and 1 week later he was discharged on crutches. He gave them up in March, 1942, and used a cane, which he still uses when walking out-of-doors. He can walk and sit with comfort, although prolonged sitting causes some local stiffness but no pain in the hip. There is occasional pain in the knee, and he limps when walking. This has now been greatly decreased by inserting a lift in the shoe. There is a 3-cm. shortening of the leg, a few degrees of internal rotation — under 5° — 35° of external rotation, 25° adduction, and 30° abduction. There is some quadriceps atrophy.

Comment. This patient not only had a painful hip condition before November, 1941, but also had a bothersome left knee that became quite stiff following the spica fixation. This knee still gives him some bother on prolonged sitting or after long walks. The hip is comfortable considering the degree of motion and amount of shortening. This result cannot be considered a return to 80 per cent normalcy, but the patient has a serviceable, painlessly functioning hip.

CASE 9. V. S., a 72-year-old man, received on September 17, 1943, a McMurray osteotomy for a painful nonunited fracture of the left femur, which was followed by a Blount blade-plate fixation. The patient suffered severe post-operative shock and had to have plasma and later two blood transfusions. An adductor tenotomy was done on October 1. The patient was discharged on December 9, using crutches. He gave up the crutches for a cane in January, 1944. He does not take long walks but when walking has no hip pain. He tires easily but can sit for protracted periods without pain. He can put on his sock and shoe easily. The leg presents 2.5-cm. shortening. There are a few degrees of internal rotation, and 35° of external rotation. Adduction is limited to 15° and abduction to 25°. There is no hip pain on the push-and-pull test.

Comment. This patient has attained a painlessly functioning hip, can walk and sit and dress himself with comfort and

has no hip pain. He is gaining strength and can take longer and longer walks.

CASE 10. J. F., a 66-year-old man, received on September 14, 1943, a McMurray osteotomy, followed by a Blount blade-plate fixation. He sat up on September 29 and walked on crutches on October 10. He was discharged on October 23 using crutches. He is still using crutches although he has some pain on protracted sitting or walking. Extreme cold gives him some local discomfort. He has done none of the daily prescribed simple exercises and cannot be persuaded to discard his crutches for a cane. He cannot put on his sock and shoe. The leg presents considerable disuse atrophy. There is practically no degree of internal rotation at the hip. The external rotation is 25°. Adduction is limited to 10°, and abduction to 30°. There is a flexion deformity of 15°. There is some pain in the hip on the push-and-pull test and on any attempt at forced rotation.

Comment. This patient, although walking for short distances, is still using crutches. He can sit with comfort for a short while but finds that long sitting causes hip pain. He also cannot dress himself. This is not a good end result.

CASE 11. J. R., a 64-year-old woman, received a McMurray osteotomy on July 10, 1942, followed by spica cast fixation until September 10. On its removal, the left-knee flexion was 30°. She walked with crutches until January, 1943, and then used a cane. At present, she uses a cane occasionally and wears a 2-cm. lift in her shoe. She has no hip pain. She did have some pain in the knee and hip on getting out of the spica, but persistent local physical therapy in the form of massage, exercises and heat, limbered up the leg so that by January, 1943, she was walking with comfort using a cane. She now does her own housework and her normal daily walking, sits with comfort, can cross her knees and dress herself and can go up and down stairs one step at a time. The leg presents a 3-cm. shortening. Abduction is limited to 25°, and adduction to 15°. There is practically no internal rotation but a good degree of external rotation. On the push-and-pull test there is no "give" or pain in the hip.

Comment. This patient finally had an excellent end result after a discouraging immediate postoperative convalescence, due chiefly to her knee.

From this series and the previously reported one, the following composite data have been gathered.

The preliminary Kirschner-wire insertion through the proposed osteotomy site, together with an immediate x-ray checkup as a guide for the osteotomy, is extremely valuable, even though it consumes an extra five minutes. It serves to place the osteotomy more accurately than does the sight-and-touch method.

From the cases treated postoperatively by the plaster-of-Paris spica fixation the following points are deduced: Despite the apparent simplicity and shortness of the operation itself, the high mortality figure shows clearly that a good deal of shock is entailed and that the patients must be chosen as carefully as for the other, more surgically devastating, reconstruction procedures. The cases chosen are those deemed good surgical risks by both the surgeon and the internist. These patients must be given good supportive treatment before and after the operation, especially those in spica fixation, who require a bed-rest period of eight to fourteen weeks, with a few more additional weeks of hospitalization. These patients as a rule leave the hospital on crutches and discard them in periods varying from a week to a year, depending on the local condition and the co-operation of the patient. Those who come to a good clinical end result following this

method — one can expect about 80 per cent to do so — walk with a slight limp owing to the resultant shortening of 2 to 3 cm. They do their daily amount of routine walking and go up and down stairs without pain but using a cane. Some have moderate pain at the end of a day after an extra-long walk. They can sit and lie with comfort, although in some cases there is a feeling of local stiffness on getting up after a protracted sitting, which, however, passes off on moving about. They can as a rule put on the stocking and shoe on the affected leg because they can flex the hip and cross the knees and adduct and externally rotate the leg. It is true that the crossing of the legs is often done with some difficulty but there is no pain. The patients can brace themselves on their legs quite well because of the presence of an average of 25 to 35° of abduction. From a local anatomic standpoint the picture is not encouraging, and all that can be said is that the formative shearing force of the femur has been transposed into a direct force that eliminates pain and gives sufficient stability and mobility at the hip joint to enable the patient to go about in a good degree of functioning comfort with the aid of a cane.

The several cases in which the Blount blade-plate internal fixation was used following the osteotomy furnished additional data. The technique part of the fixation could be made much simpler and the plate made to conform more accurately to the angular shape needed if a two-piece combination, such as the Thornton plate together with the Smith-Petersen nail, was used. This fixation does away with postoperative spica fixation and thereby allows much earlier mobility of the various joints involved in the spica fixation and, of course, much earlier application of local physical therapy. It shortens the bed-confinement period by five to eleven weeks. The final advantage of this fixation is that it prevents the slipping or sliding of the transposed femoral shaft from its moorings.

SUMMARY AND CONCLUSIONS

The McMurray osteotomy is not so simple and nonshock-producing as originally thought.

The cases chosen for the operation should be selected carefully from a local and general standpoint. There must be a fairly viable head and some femoral neck, and the patient must be a good surgical risk.

The patients should receive definite well-guided preoperative and postoperative physical therapy and general supportive medication and nutrition as outlined by the medical consultant. As the postoperative period goes into the third year or more, there may be a return of hip pain, owing to local changes in position or to bony changes. A good end result by this method gives a painlessly functioning hip, enabling the patient to sit, walk and dress with comfort. This means a great deal to a patient who

previous to the operation was having persistent local hip pain and was confined to a bed or wheel chair or compelled to use crutches. The McMurray operation, although apparently more generally adaptable than other methods, for the reconstruction of painful nonunited hips and of easier execution, and probably giving a higher percentage of painlessly functioning hips, should not be universally used in such cases. Now, as always, the surgeon ex-

perienced in such procedures should choose the one he considers best adapted to the case in hand.

VAGINAL BLEEDING FROM POTASSIUM PERMANGANATE AS AN ABORTIFACIENT

JAMES F. McDONOUGH, M.D.*

BOSTON

BURNS of the vagina and cervix due to the use of potassium permanganate tablets as an abortifacient constitute a new and gradually increasing serious complication of early pregnancy in and around Boston. Since March, 1936, when this diagnosis was first made at the Boston City Hospital, 65 cases have been treated by the Gynecological Service. Inasmuch as this entity has been so infrequently mentioned in the literature, it is the purpose of this paper to present its important features and the report of a case with serious sequelae.

A review of the literature reveals that there has been only one article written in English on this subject.¹ Between 1932 and 1940 twelve articles were written in Italian and Spanish on the use of potassium permanganate solution as a vaginal medicant.²⁻¹³ These papers mention the use of potassium permanganate tablets as an abortifacient.

A review of the records of the Gynecological Service shows that from 1936, when 3 cases were admitted, to the present there has been a gradual increase in the number of admissions for this type of case, 20 cases having been admitted in 1943. From January 1, 1930, to January 1, 1944, 15,976 cases of all types were admitted to this service. There were 65 patients with potassium permanganate burns of the vagina or cervix, representing 0.4 per cent of all admissions. During the years 1941 to 1943 these cases comprised 5 per cent of the patients admitted with threatened miscarriages.

The ages of these 65 patients varied from eighteen to thirty-eight years. There were 36 patients in the third decade, 19 in the fourth, and 9 in the second. Of the 53 patients who were multiparas, 38 had been delivered of living babies within the year previous to the date of admission to the hospital, and they all offered this as the reason for attempting to produce an abortion.

Forty-two of the patients had missed only one monthly period. The duration of the amenorrhea

in the remaining cases was as follows: two months, 14 cases; three months, 5 cases; four months, 2 cases; and five and six months, 1 case each.

No patient was ever sent to this service with the diagnosis already made. The diagnosis of the admitting physician was usually threatened miscarriage. Each patient gave a history of some menstrual irregularity, but finally admitted having inserted a "tablet" to bring on an overdue menstrual period. The usual history was that of spontaneous, painless bleeding. Eighteen patients complained of irregular bleeding for several months. The histories as given by the patients suggested all the various causes of vaginal bleeding that might be found in this age group.

Questioning concerning artificial induction of bleeding in all cases of vaginal hemorrhage is a routine matter at the time of admission, and it was only in replying to this query that 22 patients admitted using potassium permanganate. The other 43 denied the use of any method of induction, and it was only after vaginal examination and detection of the lesion that they admitted using this chemical as an abortifacient.

The onset of bleeding usually occurred within two hours of the time that the tablet was inserted.

The diagnosis is indicated by profuse bright-red bleeding, with persistence of fresh bleeding after removal of the vaginal clots. In most cases the irregularity caused by the chemical burn can be felt on the cervix or on the vaginal mucosa. Speculum examination, which is not a routine procedure in the examination of patients with threatened miscarriage on this service, reveals one or more eroded areas covered by a black eschar that are usually found in the posterior fornix on both the cervix and the vaginal mucosa. When this lesion is found on the cervix without an eschar, it resembles a severe cervical erosion or carcinomatous crater. The bleeding varies from a slow ooze to a bright-red arterial pulsating flow.

In 4 cases in which a speculum examination did not seem indicated, a diagnosis of incomplete mis-

*Formerly, resident in obstetrics and gynecology, Boston City Hospital, and instructor in obstetrics, Tufts College Medical School.

carriage was made because of the seemingly open cervical os and the misleading history of having passed fetal tissue. These patients were prepared for dilatation and curettage, and it was only after the cervix was exposed under general anesthesia that the correct diagnosis was made.

A diagnosis of pregnancy based on physical findings was made in 40 cases. In the remaining cases either the patient was not pregnant or there was not sufficient evidence to make the diagnosis.

In 10 cases it was necessary to treat the patient in the operating room, where, under general anesthesia, one to three mattress sutures were placed about the bleeding points. Thirty-four cases were treated by firmly packing the vagina for forty-eight hours. Twelve cases required rigid shock treatment, including several transfusions.

Only 6 patients were successful in producing an abortion, as evidenced by the recovery of fetal tissue. One of these patients returned when her menstrual period was overdue for a second time and admitted that she had inserted two tablets of potassium permanganate on the previous day.

The average hospital stay was five days. There were no deaths. There was no evidence of generalized toxic symptoms as the result of absorption of this chemical.

CASE REPORT

S.R., a 34-year-old tripara, was admitted with a chief complaint of vaginal bleeding. Her last menstrual period had occurred on May 11. She stated that for 6 weeks she had had slight staining, using a pad a day. She was well on going to bed the night before admission, but after having intercourse began to bleed profusely. She felt weak and fainted and was brought to the hospital in shock. She denied induction. The blood pressure was 70/30, the pulse 140, and the respirations 25.

There had been two full-term normal deliveries and one miscarriage. The last pregnancy occurred 12 months previously, and terminated in a miscarriage in the 3rd month.

Vaginal examination showed parous introitus and large blood clots in the vagina. The cervix was soft. The cervical os was closed. The uterus was the size of a 4-month pregnancy. The vaults were free. There was an irregularity of the posterior lip of cervix, extending into the vagina. Speculum examination revealed a moderate amount of blood in the vagina. On removal of the clot there was bright-red bleeding from a crater the size of a half dollar on the posterior lip of the cervix and extending into the posterior fornix.

The patient was brought to the operating room, and under nitrous oxide and oxygen anesthesia three mattress sutures were placed in the posterior lip of the cervix and a firm pack was placed in the vagina and left in place for 48 hours. The patient was transfused and treated for shock for several hours, with eventual recovery. She was discharged on the 7th hospital day.

The patient was followed in the Prenatal Clinic throughout the ensuing months of her pregnancy. It was noted that the cervix was gradually becoming distorted as a result of a cicatrix. The cervix pointed posteriorly and was continuous

with the cicatricial mass, which replaced the posterior fornix. Since the cervix was hard, and since the os was only a little larger than a pinpoint, a cesarean section was done at term.

Owing to the gradually increasing frequency of this relatively new entity, physicians, particularly those practicing in and about Boston, should consider it in a differential diagnosis of all cases of vaginal bleeding in the childbearing age. It is doubly important when one considers that in all these 65 cases not one patient gave an accurate history. As a result of the wrong diagnosis these cases may be improperly treated as threatened miscarriages and pregnancies may be unnecessarily interrupted.

There may be some significance in the fact that the first appearance of this entity in the foreign literature occurred shortly before the first case was seen at the Boston City Hospital. The patients were extremely reluctant to give the source of their fallacious information, and were surprised when they were told that potassium permanganate was not an abortifacient. It seems that an attempt should be made to educate the laity about this fallacy before use of the drug becomes more widespread.

SUMMARY

A series of 65 cases of vaginal bleeding following the use of potassium permanganate as an abortifacient is presented, and a typical case is reported.

The importance of this drug as a cause of vaginal bleeding during early pregnancy and the dangers of improper treatment based on an incorrect diagnosis are emphasized.

MEDICAL PROGRESS

PHYSICAL MEDICINE IN REHABILITATION

ARTHUR L. WATKINS, M.D.*

BOSTON

REHABILITATION has been defined as the planned attempt through the use of all recognized measures under skilled direction to restore those persons who, because of disabilities, do not assume to the greatest possible extent and at the earliest possible time that place in the productive system of society that they are potentially capable of assuming.¹ Physical medicine, which includes physical and occupational therapy, is an important adjunct to ordinary medical and surgical treatment in rehabilitation, particularly in wartime. Krusen² has reported that in civilian practice 5 to 10 per cent of all patients require some form of physical treatment. At the Mayo Clinic 8.3 per cent of all the patients who registered in 1939 were treated in the Section on Physical Medicine. In 1942 the proportion increased to 9.5 per cent. In military practice the percentage of patients who require physical rehabilitation is considerably greater. In several army hospitals 20 to 30 per cent of all patients are referred for physical therapy. As further evidence of the magnitude of these problems, it has been estimated that in 1942 there were 4,000,000 persons in the United States who suffered from physical impairment and that the annual increment was 800,000.³ Two hundred and sixty thousand of these were said to need some type of rehabilitation and 50,000 were in the process.

An over-all view of rehabilitation in various types of disorders is shown in a table in the appendix to the Tomlinson⁴ report, which was reprinted in a paper by Krusen.⁵ By referring to this table it can be seen that physical and occupational therapy have a large role in any rehabilitation scheme.

Rehabilitation is a popular topic, and many papers have been written recently on the sociologic, economic and medical aspects of the subject. One of the first books to appear was a symposium entitled *Rehabilitation of the War Injured*, edited by Doherty and Runes.⁶ Here can be found authoritative articles by an impressive group of experts giving short summaries of procedures and methods that are of value. Medical, surgical, psychiatric and physical methods of treatment are described, with their application in cases of injuries to the central nervous system and in those involving reconstructive and plastic surgery and orthopedics. A book by Davis⁷ is a valuable guide to treatment of neuro-psychiatric disorders and is based on the author's

wide experience in the Veterans' Administration Facility. Hudson and Fish's⁸ *Occupational Therapy in the Treatment of the Tuberculous Patient* is recommended to physicians interested in this field, although it is primarily written for students of occupational therapy. The more technical aspects of physical therapy, particularly mechanotherapy, are described in detail by Smith⁹ in *Rehabilitation, Re-education and Remedial Exercise*. A short manual by various authors entitled *After-Care and Rehabilitation*, edited by Rolleston and Moncrieff,¹⁰ also gives detailed information on physical-medicine procedures. Three new books have appeared, *Physical Medicine in General Practice*, by Bierman,¹¹ *Technic of Electrotherapy*, by Osborne and Holmquest,¹² and *Manual of Physical Medicine* by Kovacs.¹³ Especially recommended are the manuals on physical therapy and occupational therapy available in reprint form through the American Medical Association, which may serve as practical guides to physicians in the armed services.

PHYSICAL MEDICINE FOR TRAUMATIC CONDITIONS

In military practice the lesions most frequently benefited by physical medicine are traumatic in origin. Krusen² has divided these into two large groups — trauma of bones and joints, including fractures, dislocations, stiff joints, bone grafts and traumatic arthritis, and trauma of soft tissues, including scars (particularly of amputation stumps), contusions and lacerations of muscles and tendons, postural strains (particularly backache and flat-foot), paralysis (especially as a result of peripheral nerve injuries) and tendon transplantations.

Although no striking changes in technic have recently been developed, appreciation of the benefits to be derived from physical therapy in traumatic conditions is not yet widely disseminated throughout the medical profession as a whole. In summarizing the principles of physical medicine as described by Pemberton,¹⁴ it can be stated that the central agencies of physical therapy consist of heat, massage, rest and exercise. Exposure to heat is accompanied by a rise in body temperature, an increase in the heart rate and peripheral vasodilatation. A great increase in rate of circulation occurs throughout the body, with leukocyte diapedesis into neighboring tissue, and hence phagocytosis and other influences on fixed tissues. Total metabolic activity is increased and the lymph flow is accelerated. The use of heat locally and sometimes systemically paves the way for massage.

*Chief, Department of Physical Medicine, Massachusetts General Hospital; assistant in medicine, Harvard Medical School.

About 25 per cent of the blood of the body is in the capillary beds, many of which are near the surface or at the periphery. Stroking of capillary beds induces changes in the caliber of the capillary vessels, an acceleration in the rate of blood flow through them, a rise in the peripheral blood-cell count and a migration of leukocytes. Some cellular and acinous contents of certain organs can be expressed or changed in distribution. There is no production of lactic acid following massage, such as accompanies voluntary use of muscle, or of alkalosis, such as follows exposure to heat. Extravasations of blood or débris into tissue from trauma can be removed by massage more quickly than would otherwise occur. Improper use of massage, may, of course, draw blood away from regions greatly needing it and so lead to fatigue and depletion. Exercise, which affords the only means of developing muscle, has some of the effects on capillary beds produced by heat and massage. So-called "postural exercise," involving deep breathing and achievement and maintenance of better posture in recumbency, goes far to compensate for loss of bodily activity and has great value for persons confined to bed or a sedentary life. Rest is also important in physical therapy. Pemberton also states that there is probably no other field of medicine in which early and full grasp of the principles at stake would have equally significant results in returning soldiers to duty and in reducing invalidism. Some of the ordinary applications of physical therapy in traumatic surgery will be described in more detail.

Fractures

Successful treatment of fractures is not based solely on securing bony union but also on the rapidity with which full working function is obtained. The type of aftercare of fractures may influence considerably the functional result, particularly the speed of recovery.¹⁵ The proper aftercare of a fracture consists of maintenance of fixation until union has occurred, early restoration of efficient circulation, development or preservation of muscular tonus and power and guidance in obtaining normal co-ordinated skillful joint motion. The purposes of physical therapy have been outlined as follows:

Promoting the early absorption of hemorrhage and traumatic exudate; relaxation of muscle spasm to relieve pain and discomfort; re-establishment of normal circulatory conditions in the affected extremity, blood stream and lymphatics, which ensures a more rapid and complete healing of the fracture; and building up in the muscles of the extremity that tone and flexibility so necessary to normal use. These effects are brought about by physical agents acting on the neuromuscular and neurovascular reflex mechanisms and through stimulation of muscles by physical means or voluntary action.¹⁶

To accomplish these purposes the following physical agents are used: heat, massage, muscular stimulation and occupational therapy. Heat may be applied in the form of radiant-heat lamps, whirl-

pool baths, hot packs or diathermy, preferably of low intensity and sustained duration. Massage consists of light stroking alone in the early stages and deeper stroking later, it being borne in mind that the beneficial effects are obtained more by reflex stimulation than mechanical force. Under muscular stimulation, contractions are obtained preferably by inciting voluntary efforts, either within a guided range of motion or by stationary contractions, such as so-called "setting exercises." In some cases, particularly those in which prolonged immobilization is necessary, electrical stimulation with a tetanizing current (sinusoidal or faradic) is a valuable aid in preventing muscle atrophy and fibrosis and in improving circulation. When a proper degree of firm union is obtained, the patient must be instructed and encouraged in graded active and functional use of the affected parts. Occupational therapy emphasizes the value of functional, properly graded activities as incentives to the development of strength and skill and as a means of overcoming psychologic handicaps to recovery.

Sprains and Dislocations

Cold rather than heat, compression bandages and elevation are recommended for the immediate treatment of sprains. Later the measures described for aftercare of fractures are suitable, with proper grading of exercises an essential feature. When joints have become stiff from traumatic arthritis, chronic bursitis or other cause, too much must not be expected of heat and massage. Return of function is dependent on proper stretching by active and assisted exercises. At times this may be supplemented by splinting and traction.

Scar Contractures

Limitation of motion secondary to contracture of scar tissue after burns or other soft-tissue injuries may require prolonged physical therapy. In case of hand involvement specially designed splints allowing motion have been described.^{17, 18} Mild heat in the form of a whirlpool bath or paraffin bath has been recommended, as well as a special type of massage to improve circulation and loosen adhesions, followed by active exercises and graded functional activity as prescribed in occupational therapy.¹⁹

Amputations

In preparing stumps for early use, heat, massage and exercises are helpful.²⁰ Moderate radiant heat may be used to stimulate circulation, and also whirlpool baths, with avoidance of excessive use and softening of the skin. Massage also aids in promoting circulation. Of special importance is a program of exercises to develop the strength of the musculature. These are graded to include resistive exercises four times daily. Physical therapists should also instruct patients in the mechanics of using an

artificial limb and walking with walkers, crutches and canes.

Peripheral-Nerve Injuries

Physical therapy in injuries to the peripheral nerves includes the use of proper splinting to prevent overstretching of paralyzed muscles by gravity or antagonistic strong muscles.²¹ This should not be constant, since severe joint contractures may thus develop. In cases of paralysis splints should be removed for heat and massage to improve circulation and for passive exercise to prevent joint stiffness. Recent studies have indicated that adequate stimulation with low-frequency interrupted direct or alternating currents is useful in lessening atrophy, preventing fibrosis and hastening return of function with reinnervation.^{22, 23} Quantitative electrical tests familiar to the specialist in physical medicine are also of aid in evaluating the extent of neural damage and in following the progress of regeneration.^{24, 25}

Spinal-Cord Injuries

The treatment of injuries to the cervical, thoracic and lumbosacral cord has been adequately described in recent reports by Munro.^{26, 27} The usual physical therapeutic measures useful in spastic paralysis are employed.²⁸ The frequent finding of atrophic stiff hands in the cervical injuries was noted by Munro, who suggested that it might be due in part to vitamin deficiency. He recommends giving intensive treatment with vitamin B complex, in addition to early and continuous physical therapy.

HEALTH RESORTS

British physicians have found that health resorts are invaluable as centers for those disabled in war. In the United States, also, rehabilitation centers have been set up in such localities. The United States Army Medical Corps, for example, has established them at White Sulphur Springs, West Virginia, Colorado Springs and Denver, Colorado, Hot Springs, Arkansas, Battle Creek, Michigan, Swananoa (near Asheville), North Carolina, Tucson, Arizona, and Miami, Florida. The Bureau of Medicine and Surgery of the United States Navy has established hospitals at Asheville, North Carolina, Yosemite, California, Glenwood Springs, Colorado, and Sun Valley, Idaho. The Veterans Administration, it is said, is contemplating the establishment of hospitals at such health resorts as Saratoga Springs, New York, Hot Springs, Utah, Hot Springs, South Dakota, Bay Pines, Florida, and Mineral Springs, Texas.

The exact sphere of usefulness of treatment in a health resort as part of a broad plan of total rehabilitation has been shown by Krusen.⁵ He outlines the steps in a complete plan for total rehabilitation as follows: immediate emergency care,

secondary emergency care, care during transportation, general hospital care, care in rehabilitation centers, vocational guidance, vocational training, selective placement and industrial rehabilitation. He states that health resorts will be utilized most frequently as rehabilitation centers, with vocational guidance and vocational training included. In some instances health resorts can fit into general hospital care, the hospital being located at the resort. Selective placement can occasionally be arranged at the health resort before establishing a permanent home in civil life.

In order that American physicians may have more accurate knowledge about spa therapy and its range of usefulness, a series of articles have been published by distinguished specialists in the field under the auspices of the Committee on Health Resorts of the American Medical Association. In these papers are discussed the effects of climate on disease^{29, 30} the role of rest, exercise and diet,³¹ underwater therapy,³² the biologic action of trace elements³³ and the nature of natural therapeutic agents, such as mineral waters and peloids.³⁴ Articles are also devoted to the physical equipment,^{35, 36} types of treatment available,^{37, 38} administration³⁹ and economic aspects.⁴⁰ The subject of hydrology and spa therapy is in fact deemed so important that plans have been made to establish a research center in physical medicine, with emphasis on acquiring more fundamental knowledge relative to this type of therapy.⁴¹

CONVALESCENT RECONDITIONING

An aspect of rehabilitation that is receiving special attention in the armed services is that of planned convalescent care. Thorndike⁴² has stated:

The Surgeon General's reconditioning program is divided into four main phases: physical, educational, occupational and recreational. The physical portion of the program is designed to allay the deteriorated factors coincident with recumbency in bed by use of special bed exercises designed to maintain body tone and vigor and, when indicated, is often focused to strengthen a particular portion of the body. As the patient's strength increases and he becomes ambulant, these exercises are gradually increased in tempo and dosage and are supplemented by various types of athletic games and recreational sports. Physical therapy, when indicated, is co-ordinated with this regimen. Occupational therapy is an important part of the treatment of many patients. It is used both as a functional and a diversional type of therapy. Efforts are made to integrate closely the educational activities with the occupational therapy in order to double the effect of each. Co-ordination of occupational therapy with physical therapy is being effected with good results.

Huddleston⁴³ has reported the effective use of a convalescent ward at the Fitzsimons General Hospital. Drewyer⁴⁴ and Lowman⁴⁵ have described similar arrangements in the Navy. Special programs have been outlined for psychiatric casualties.⁴⁶ The methods in use in the Army Air Forces have been especially efficient.⁴¹

Civilian hospitals will do well to incorporate applicable portions of these plans for convalescent care, both to ease demand of beds by speedy convalescence and for the welfare of the patient. The need for research in this field is made apparent by a series of papers indicating the ill effects of complete bed rest.⁴⁷⁻⁵² Hansson⁵³ has shown how physical therapy may be utilized to counteract the bad effects of rest and to "turn out a discharged patient with adequate circulation, better muscular tone, better posture, a normal functioning gastrointestinal tract, better skin and a mind that is mentally alert instead of depressed."

A closely related subject is that of the physical fitness of so-called "normal" persons. Its importance is indicated from the finding that one out of four of the teen-age registrants fails to pass the Selective Service examination. Studies have been made in determining methods to evaluate physical fitness and to quantitate the effects of training.⁶⁴ Already plans have been made to establish a national program for physical fitness.⁶⁵

INDUSTRIAL REHABILITATION

Industrial concerns and insurance companies are beginning to realize the importance of medical care that goes beyond hospital medicine and surgery and includes convalescent care and industrial rehabilitation. Howitt⁵⁶ has described a center in England constructed on the lines adopted for army practice. Aitken,⁵⁷ Coulter,⁵⁸ Zeiter⁵⁹ and others^{60, 61} have reported similar setups established in this country. Both physical and occupational therapy are extensively employed, particularly in the early stages after injury. Activities are later directed toward vocational guidance and placement in jobs appropriate for the degree of handicap. The program of the Caterpillar Tractor Company, including job analysis and the use of 800 handicapped employees, is an outstanding example of success in rehabilitation.⁶²

* * *

The wide scope of physical rehabilitation and its importance in wartime are now apparent. One of the most serious needs is trained personnel for convalescent centers. Teachers are also needed to instruct a new group of specialists in this field. Already teaching and research centers in physical medicine have been established for this purpose in a number of leading university medical centers. The old term "physical therapy" has now been largely replaced and a new specialty, "physical medicine," is being established. A comprehensive and enlarged view of physical medicine in rehabilitation can be gained from the following quotation:

It seems that there are two definite phases: first, physical medicine as it pertains to definitive treatment and how it can be utilized by the physician in the diagnosis and treatment of disease; secondly, — and which I think is the more or less new concept as far as the general medical profession is concerned, — its utilization in the broad field, taking up the dead space between definitive care and ability

to return to productive work, the setup for retraining and reconditioning, medicine and its relation to environment, occupation, social status and so forth. It is going to take physicians with real training and background to meet this special need; it should be the broadest of all medical specialties, utilizing as a basis for physical medicine the great potentialities of oneself. This would be more or less the science of how to use these potentialities and the art of such application.⁶³

CASE 31071

PRESENTATION OF CASE

A four-and-a-half-month-old infant was admitted to the hospital because of opisthotonos and failure to gain weight.

The infant was born six weeks prematurely after a normal labor of five and a half hours. The pregnancy was complicated by toxemic symptoms. The birth weight was 5½ pounds. After three and a half weeks in an incubator the child was discharged home, but was a poor feeder and gained weight very slowly, the weight on admission to this hospital being only 8¼ pounds. The mother noted that the child cried a great deal and often turned blue after a crying spell. The child also tended to lie in an opisthotonic position, with the back arched and the head held well back, especially when crying. He could support his head. There was no history of jaundice or convulsions. On several occasions the child had had a running nose but had never been febrile.

Physical examination revealed a spastic, irritable child, often opisthotonic and crying almost constantly; there was a click-clack sound to the breathing after the crying ceased. There was slight cyanosis of the face, especially about the mouth and most marked during crying spells. The skin was clear. The muscles appeared unusually well developed. The head was malformed, with a definite bulge over the

occipital region. There was considerable exophthalmos, estimated at about 4 mm. The pupils reacted normally, and the fundi were negative. The ears were negative. There was questionable enlargement of the lateral lobes of the thyroid gland, and a thrill and bruit were noted over this area; the bruit could also be heard in the lower temporal regions. The lungs were clear. Examination of the heart revealed the point of maximum impulse to lie just below and beyond the nipple line. The rate was rapid and regular. A systolic murmur was heard all over the precordium, loudest in the fourth and fifth intercostal spaces, just lateral to the left sternal border; it was transmitted to the neck and back, shifting somewhat with change in position. The pulmonic second sound was greater than the aortic, but both were prominent. The liver was felt three fingerbreadths below the costal margin, and the spleen was palpable. All the extremities were spastic, the legs more so than the arms. The deep tendon reflexes, especially those of the lower extremities, were exaggerated. The Babinski, Oppenheim and Gordon signs were positive bilaterally. The abdominal reflexes were absent, but other superficial reflexes were normal.

The temperature was 100°F, the pulse 145, and the respirations 45. The blood pressure was 146 systolic, 40 diastolic.

Examination of the blood on admission revealed a red-cell count of 4,500,000, with 90 per cent hemoglobin, but subsequent counts averaged about 3,500,000, with 70 per cent hemoglobin. The white-cell count was 14,000, with 59 per cent neutrophils, 27 per cent lymphocytes, 7 per cent monocytes, 1 per cent eosinophils, 1 per cent basophils and 3 per cent myelocytes. The red cells and platelets appeared normal on smear. The urine was negative. The bleeding and clotting times were both within normal limits. The serum nonprotein nitrogen was 30 mg. per 100 cc., the protein 6.4 gm., the calcium 9.8 mg., the phosphorus 6.1 mg. and the alkaline phosphatase 3.9 Bodansky units. The sodium was 136.1 milliequiv. per liter, the potassium 5.6 milliequiv., and

*On leave of absence

the chloride 98 milliequiv. The van den Bergh reaction and the prothrombin time were normal. Nose and throat cultures were negative, as were cultures of the blood, spinal fluid and stools. A blood Hinton test, including dilutions, was negative. Determinations of the serum protein-bound iodine on the third and fourth hospital days were 9 and 9.3 microgm. per 100 cc., respectively (these are borderline, high-normal values).

A roentgenogram of the chest revealed marked enlargement of the heart to the left but no definite evidence of transposition of the vessels or engorgement of the pulmonary artery. The lungs were clear. Roentgenographic examination of the skull revealed bones of normal texture and density. The posterior fontanelle was closed, and the anterior fontanelle open, and there was no separation of the sutures. Lateral examination of the neck revealed widening of the posterior pharyngeal wall without tracheal obstruction. The thoracolumbar spine and bones of the lower legs were normal.

A lumbar puncture on admission yielded clear fluid dripping out slowly and containing 70 fresh (uncrenated) red cells and 1 to 2 lymphocytes per cubic millimeter. The Wassermann test was negative, and the sugar and protein were normal.

The patient's temperature ranged between 100 and 103°F. for the first four days, thereafter remaining approximately normal except for a brief rise to 103°F. on the seventh hospital day. The pulse continued to range between 120 and 180, and the respirations between 35 and 80. The blood pressure varied considerably, with high systolic and low diastolic pressures; one observer reported a reading of 300 systolic, 0 diastolic, on one occasion.

The child was given 2 cc. of paraldehyde in oil every four hours for sedation, 8 mg. of sodium phenobarbital being substituted after a few days. A diarrhea with three to six loose stools daily developed on the third hospital day and continued thereafter. Six thousand units of penicillin was administered every three hours over a period of nine days, and because of the diarrhea and poor appetite, the child was maintained for short periods on parenteral fluids. On the fifth hospital day thiouracil therapy was begun, 25 mg. being administered every six hours, and on the seventh day 2 drops of saturated potassium iodide solution was instituted daily as well. Although some observers thought that the size of the thyroid gland was diminishing, irritability, hypertonicity and frequent opisthotonic spasm continued.

On the twenty-first hospital day the child suddenly went into collapse, with gasping respirations and cyanosis. The pulse fell to 88, and the blood pressure to 78 systolic, 50 diastolic, and he seemed more relaxed than previously. A lumbar puncture at that time revealed fluid containing 500 fresh red cells but no white cells per cubic millimeter, 3 cc. of fluid being removed only with great difficulty. Ven-

tricular taps on the following day revealed slightly bloody fluid containing 3800 fresh red cells per cubic millimeter on the left and cloudy fluid containing 800 fresh red cells on the right. The Pandy test was negative, and the sugar normal.

The child was treated with oxygen, 10 cc. of adrenocortical extract and glucose intravenously. During the ensuing thirty hours the child had frequent attacks of breathlessness and cyanosis and the pulse fell to 40 in spite of various stimulants. Death occurred on the twenty-third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT WILLIAMS*: The nature and number of the observations made in this case are such that in the search for their solution one is led through most of the main general divisions of pathology. It is necessary to give some consideration to traumatic birth injuries, infections, neoplasms, metabolic disorders and congenital anomalies. The accumulated data in the case are such as to make one consider direct or indirect involvement of widespread sites in the body. There are suggestions of disorders in the head, neck, chest and abdomen. At the outset, however, it should be mentioned that in children, particularly in infants, one may observe symptoms and signs in several systems other than the ones directly involved. For example you will recall how commonly one sees evidence of central-nervous-system stimulation and gastrointestinal-tract alterations in a large number of diseases of childhood that cause no direct involvement of these systems. It is also well to recall that, for a given amount of disease, children respond much more markedly with changes in temperature, pulse rate, blood pressure and respiratory rate. Moreover, in some respects the physical signs in normal, as well as in abnormal children, differ from those of adults. For example, the liver edge is more frequently palpated in normal children. The tendon reflexes are often exaggerated, the abdominals absent, and the Babinski positive. In infants there may be serious cardiac lesions producing a paucity of physical signs, whereas in adults the same type of lesion usually causes pronounced signs. Finally, a young child is not likely to have multiple diseases, although there may be multiple disturbances of the same general nature.

With these general principles in mind we may next consider critically the data presented chiefly in the light of anatomic disturbances and without an attempt to integrate the entire picture. Alterations in the nervous system should be considered seriously because of the marked irritability, the hypertonicity, the opisthotonos, the bulging in the occipital region, the hyperactive reflexes, the positive Babinski, Gordon and Oppenheimer signs and the bloody cerebrospinal fluid. The frequent insignificance of many of these signs, however, has

*Associate in medicine, Harvard Medical School; junior visiting physician, Boston City Hospital

already been discussed. It can also be pointed out that there is a condition, designated as the hypertonic infant, in which no significant pathologic alteration has, to my knowledge, been found, with some of the characteristics of the case under consideration: irritability, prolonged crying, hyperactive tendon reflexes, muscle spasm, opisthotonos, flexion of the arms and legs, clenching of the hands, diarrhea and a slow gain in weight. It is to be emphasized that although the cerebrospinal fluid was bloody on four occasions, each time the red cells appeared fresh, and there was no xanthochromia, increased protein or increased white-cell count. Furthermore, there was no evidence of increased spinal-fluid pressure. Therefore, although the central-nervous-system changes are suggestive of disease, they are not convincing.

Exophthalmos is often a helpful sign, but it may occasionally be misleading. In addition to being a manifestation of Graves's disease, it may be due to tumors or infections in the orbit, increased venous pressure, small orbits and retention of orbital fluid, as in nephritis and hypertension. It may also be a racial characteristic, occurring especially in Italians. The equality of the exophthalmos on the two sides, the absence of obvious edema of the orbits, the absence of papilledema, and the absence of evidence of abnormal masses in the cranium help to reduce the etiologic factors that must be considered.

In considering the bruit in the neck it must be stressed that, whereas it was heard over the thyroid gland, it was also heard at the base of the skull. Whether the bruit was of the same order as the murmur heard in the neck and back and over the precordium must be borne in mind. It is of significance that no masses or dilated vessels were palpated in the neck or elsewhere. The thyroid gland was questionably enlarged, but whether the enlargement was due to Graves's disease, to increased vascularity of the neck or to some other cause must be considered.

The changes in the cardiovascular system are the most convincing of any. There is no reasonable doubt about the heart being distinctly enlarged. The repeated blood-pressure estimations revealed a distinct elevation in the systolic pressure and a drop in the diastolic pressure. The murmur heard over the lower precordial region, back and neck was of sufficient intensity to appear significant. The pronounced tachycardia, tachypnea and some cyanosis indicate that the cardiovascular system was burdened.

The liver may be considered to have been slightly enlarged, as perhaps the spleen.

Aside from the roentgenograms the laboratory findings are of no particular aid, except by their negative character.

In the differential diagnosis I have given some consideration to a rather large number of diverse conditions, among them being brain tumor, various

infections, traumatic injuries, Graves's disease, von Gierke's disease, the infantile type of Gaucher's disease, Niemann-Pick's disease, pheochromocytoma, venous hums, arteriovenous aneurysm, patent ductus arteriosus, coarctation of the aorta, patent septal defects and a number of other congenital heart diseases. To be sure, I readily dismissed many of these entities from consideration since, although they satisfied some criteria, they were at a loss in explaining others. Since most of the positive data had reference to the cardiovascular system, and since this was an infant who apparently had never been well, chief consideration was given to congenital cardiovascular anomalies. The chief problem is to explain a large heart with presumably competent valves but with peripheral manifestations of aortic insufficiency and with murmurs or bruits over the lower precordium, back, neck and temporal regions. Lest I have been too hasty in discarding some of the data, however, I shall briefly review the features of this case in the light of other diseases.

Let us consider brain tumor. There were no convincing neurologic signs of a brain tumor and no definite abnormalities of the cerebrospinal fluid—at least the abnormalities present are open to question. There was a negative skull plate. There were many positive cardiovascular signs, indicating that there was a great deal of trouble other than what might have been caused by a brain tumor.

Infection is suggested by the fever, the tachycardia and so forth; but against infection are the negative cultures from many sites. Infection could not explain many of the cardiovascular findings, but it still might be considered as the cause of the terminal event.

The next condition to discuss is trauma. This is considered particularly because of its etiologic significance in arteriovenous aneurysms. There was no history of injury at birth or subsequently, and there was no definite physical evidence of it.

Metabolic disorders might be discussed next. The first among these is thyrotoxicosis. As a matter of fact, as one rapidly reads the characteristics of this infant's disease there are many features that one might consider as favoring thyrotoxicosis. For example, the four cardinal features of thyrotoxicosis in children are readily apparent: exophthalmos, nervousness, questionable goiter and tachycardia. Against this diagnosis, however, are the extreme rarity of the disease at this age, the essentially normal protein-bound iodine and the fact that the response to treatment was not particularly good. Furthermore, thyrotoxicosis will by no means explain all the cardiovascular features.

The next condition for consideration is von Gierke's or glycogen-storage disease. In favor of it is the extremely large heart with some enlargement of the liver and perhaps splenomegaly. It is also of some little interest in this connection that the child

was said to have been well developed muscularly; in this disease one may actually get hypertrophy of some of the muscles. Von Gierke's disease, however, does not explain the wide pulse pressure or the murmur.

This child had certain features that one observes commonly with Gaucher's disease, although they are not pathognomonic of the disease, these being the rapid course of the disease, the nervous symptoms, the slow weight gain, the enlarged liver and spleen, the opisthotonos, the increased reflexes and the spasticity of the limbs. But I find it difficult to explain the cardiovascular findings on this basis.

Some of the comments that I have made on Gaucher's disease apply to Niemann-Pick's disease and Schüller-Christian's disease. The latter need not be given much consideration. It might explain the exophthalmos, but there was no defect in the bones, and no diabetes insipidus, and this disease would not explain the cardiovascular changes.

Finally we come to the congenital anomalies. As I have mentioned before, the fact that the child's trouble dated from birth and the fact that most of the features seemed to be related to the cardiovascular system make one begin to give great emphasis to the possibility that there was a congenital anomaly somewhere in the vascular system.

First we might consider the possibility of a cranial arteriovenous aneurysm. Although I have cast some doubt about the validity of the neurologic data, both clinical and laboratory, and whereas there is good reason for attributing significance to certain specific observations when one considers them as a whole, they do indicate that there might have been organic disease somewhere in the cranium. Arteriovenous aneurysm in the cranium would explain the bruit that was heard at the base of the brain. Such a bruit is one of the most characteristic features of such a lesion. It might also explain the exophthalmos. To be sure, when there is exophthalmos on the basis of arteriovenous trouble it is apt to be unilateral, but I can conceive how it could be bilateral. Furthermore, one can consider the peripheral vascular manifestations, simulating aortic insufficiency, as being on the basis of arteriovenous aneurysm, but I must say that the peripheral changes are quite pronounced and out of proportion to what one usually observes with such an abnormality.

We might consider a cervical arteriovenous aneurysm or one in the extremities. Such an entity would account for the high pulse pressure, with a high systolic and a low diastolic pressure, cardiac dilatation and hypertrophy, cyanosis, tachycardia and the bruit in the neck. Furthermore, in peripheral arteriovenous aneurysm, murmurs in the heart have been described, even though there is no direct abnormality in the heart itself, although, to be sure, these murmurs are usually not very loud. Against the possibility of arteriovenous aneurysm

in these sites is the fact that we have no mention of evidence of localized venous engorgement or edema. I believe that, with all the peripheral alterations in the vascular system, one should be able, particularly in a small child, to palpate the arteriovenous mass, unless it was hidden in the brain or in the thorax.

We may consider a patent ductus, which is also an arteriovenous aneurysm but is located in the chest. In favor of this are the signs of an arteriovenous aneurysm in the absence of a peripheral arteriovenous aneurysm. There are loud pulmonic and aortic second sounds, with the pulmonic being louder than the aortic. With patent ductus arteriosus the most classic feature is a machinery-like murmur, which one hears almost always in the second left interspace, close to the sternum. That murmur is absent here. The second most important point, a characteristic configuration of the heart and great vessels, was not present in this case.

Coarctation of the aorta should be considered because of the high systolic pressure that was found in a child that had a good chance to have a vascular anomaly. The diastolic pressure, however, was definitely low, and unless there was some other abnormality associated with coarctation, the diastolic pressure should have been normal, if not elevated. There were no murmurs or other good physical signs indicating the presence of the stenosis. Because of the relatively loud murmur heard in the fourth and fifth interspaces parasternally on the left, and because of the absence of good evidence for valvular disease and murmurs in the region of the base of the heart, one should probably also consider the possibility of interventricular septal defect. This child could well have had this abnormality. There is not much evidence for it, but it is difficult to rule it out.

In conclusion, on considering the picture as a whole, it seems to me that the data indicate that this child had an arteriovenous shunt, accompanied by cardiac dilatation and hypertrophy. The evidence available does not permit one to say specifically where the shunt was located. The best I can say is that it was either in the cranium or in the thorax.

DR. NATHAN B. TALBOT: I saw this child during the early part of the hospital stay and am frank to admit that clinically, with the aid of numerous consultants, it was impossible to come to any definite conclusion. Although we carefully considered the possibility that the infant had thyrotoxicosis, we also were at times worried that there was a significant intracranial lesion of some type.

DR. CLEMENS E. BENDA: I think that the neurologic symptoms did not attract sufficient attention. Even if the positive Babinski sign was of little significance, the child had opisthotonos and severe spasticity. There was flexion of the legs and of the arms, with clenched fists. The head was bent back-

ward, and the eyes showed protrusion, which is so frequently seen in infants with intracranial hemorrhage, as demonstrated by Dr. Ingraham.*

I do not see how anyone can explain the neurologic symptoms on the basis of anything except an intracranial lesion, and I do not believe that one can disregard the possibility of an intracranial hemorrhage. Although prematurity in itself is of no pathological significance, many studies have

dependent of hyperthyroidism. The child had definite exophthalmos, particularly marked in the side view, and a loud bruit in the neck; he was extremely active and underweight. I believe that I was alone in thinking that the thyroid gland was enlarged—I was quite sure that both lobes were increased in size. The child seemed to possess all the criteria necessary to make a diagnosis of Graves's disease. When the blood iodine came back as 9

FIGURE 1.

demonstrated that premature babies are particularly likely to have intracranial hemorrhages because of the immaturity of their vascular system. The frequency of intracranial hemorrhages increases with the decrease in birth weight. For example, 76 per cent of all premature babies weighing less than 3½ pounds were found to have some kind of intracranial hemorrhage. Since this child did not have immediate dramatic symptoms after birth it is probable that the lesion was related to the venous system, from which blood was seeping out slowly, the difficulty not becoming recognizable until several weeks after birth.

DR. JACOB LERMAN: When I saw the youngster I thought that the most important diagnosis to be considered was hyperthyroidism, with or without an accompanying neurologic disorder. In other words, the neurologic picture seemed to be in-

microgm. per 100 cc., which is a high normal, it seemed to be confirmatory of the diagnosis. It is true that in the end the patient did not do well, but in the first few days he seemed to improve and, as I recall, the impression of hyperthyroidism became more plausible. Such a diagnosis, however, did not explain his other manifestations.

DR. TALBOT: I can back up Dr. Lerman's remarks by the statement that this baby presented the most extraordinary degree of hyperactivity, seemingly not only physical but also, one might say, metabolic.

CLINICAL DIAGNOSIS

Thyrotoxicosis.

DR. WILLIAMS'S DIAGNOSES

Arteriovenous aneurysm, cranial or thoracic.
Cardiac dilatation and hypertrophy.
Terminal infection.

*Ingraham, F. D., and Matson, D. D. Subdural hematoma in infancy. *J. Pediatr.* 23:1-37, 1944.

ANATOMICAL DIAGNOSES

Cerebral arteriovenous aneurysm.
 Cardiac hypertrophy and dilatation.
 Bronchopneumonia.
 Pulmonary edema.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this child showed a thyroid gland that weighed 1.4 gm. and, so far as we could tell, showed no evidence of hyperplasia or hyperactivity, such as one would see in hyperthyroidism. The heart was more than normal in size, weighing 55 gm., the normal weight of the heart in a child of this age being about 20 gm. There was hypertrophy of the left ventricle, but no anomalies. The child had a terminal bronchopneumonia, a bit suggestive of the aspirative type; the bronchi were filled with purulent exudate, as were the surrounding alveoli. There was also a rather severe pulmonary edema. The real disease was in the cranium, however, and I shall ask Dr. Kubik to describe it.

DR. CHARLES S. KUBIK: I should like to congratulate Dr. Williams on his excellent discussion.

The left occipital lobe was absent—whether through degeneration or lack of development is not altogether clear. At the posterior extremity of the defective left cerebral hemisphere there was a cluster of thin-walled, tortuous blood vessels that communicated through a large venous channel with the superior longitudinal sinus and, through arterial branches, with the left anterior cerebral and left posterior cerebral arteries. All the arteries supplying the arteriovenous aneurysm with blood were enlarged to at least three or four times the size of the corresponding normal arteries—as is the rule with any artery proximal to an arteriovenous fistula. The arteries affected were both vertebrals, the basilar, both internal carotids, the left anterior cerebral, the left posterior cerebral and the right anterior cerebral only as far as the anterior communicating artery (Fig. 1). Cardiac enlargement is also found in these cases.

Two patients with similar arteriovenous aneurysms, having connections between the anterior and posterior cerebral arteries and the superior longitudinal sinus, have come to autopsy at this hospital. One was a man in his early twenties, and the other was a man about sixty years old. The former died as the result of hemorrhage from the abnormal vessels. The other had a subdural hematoma. In both cases, calcification of the abnormal tortuous vessels was visible by x-ray. In still another case the patient was a woman of twenty-eight with multiple arterial connections between a greatly enlarged lateral sinus and the basilar, middle meningeal and occipital arteries.

Thus patients with intracranial arteriovenous aneurysms may live many years, and I should not

suppose that death in the present case was caused by the arteriovenous aneurysm. A possible explanation of exophthalmos was increased venous pressure transmitted from the superior longitudinal sinus through anastomotic veins to the cavernous sinuses and from there to the ophthalmic veins.

CASE 31072

PRESENTATION OF CASE

A sixty-four-year-old married multiparous woman was admitted to the hospital with pain in the right lower quadrant of the abdomen.

About one year prior to admission the patient noted an intermittent dull aching pain in the abdomen, at first centered about the umbilicus but soon localizing in the right lower quadrant. It was associated with some tenderness and accompanied by nausea. There was no vomiting, diarrhea, fever or chills. This pain lasted about six days, after which all symptoms disappeared. During the following year she had two or three similar episodes, each lasting about a week. During some of them she was bedridden. She kept about her housework but complained to her family of "soreness in the right side." Seven weeks prior to admission she noted a recurrence of the distress, at first intense about the umbilical area and finally localizing as "soreness" in the right lower quadrant. This attack lasted until the time of admission. She was nauseated mildly on two occasions, never vomited and experienced no chills or fever. She had tended to be constipated for years, and there had been no change in this habit. She took laxatives sporadically. She had never noticed any blood.

Ten years prior to admission she had had a hemorrhoidectomy. One of her sisters had died of tuberculosis.

Physical examination revealed a well-developed and well-nourished woman in no acute distress. The lungs were clear. The heart revealed questionable enlargement to percussion. Systolic murmurs were heard at the apex and over the aortic area, and systolic and diastolic murmurs at about the level of the third interspace to the left of the sternum. There was slight tenderness over a definite mass on deep palpation in the right lower quadrant.

The temperature, pulse and respirations were normal. The blood pressure was 130 systolic, 80 diastolic.

The hemoglobin was 13.6 gm. The urine—a voided specimen—had a specific gravity of 1.023, with a + test for albumin and many white cells in the sediment. A stool examination was guaiac negative. A blood Hinton test was negative.

A roentgenogram of the chest revealed increased pulmonary markings throughout. The heart was enlarged, principally in the region of the left ven-

tricle. The aorta was somewhat dilated, and a double ring of calcium was visible at the arch. An intravenous pyelogram revealed some lateral displacement of the right kidney, but no other abnormalities were observed. A round shadow was visible in the right upper quadrant, consistent with a gallstone. The lumbar spine showed mild degenerative changes, all the bone appearing decalcified. A barium enema revealed a retrocecal appendix and an irregular defect lying along the posterior aspect of the cecum and ascending colon corresponding to the palpable mass. The colon was somewhat fixed at that point, but the mucosal pattern appeared to be intact.

On the fifth hospital day a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: I should like to look at the x-ray films, although, as I have said many times, I am never sure whether Dr. Holmes is going to help or disturb me by showing them.

DR. GEORGE W. HOLMES: You should have been here a short while ago when I was discussing the differential diagnosis of a case and had my first opportunity of making the same statement to the surgeons.

The first thing I notice is that in this intravenous pyelogram there is evidence that the patient did not concentrate urine well. The kidneys are about normal in size, and I do not see any definite evidence of tumor. In the chest film I observe a ring of calcification in the aorta and a great deal of arteriosclerosis, with some tortuosity of the aorta and enlargement of the left side of the heart. This picture can go with hypertensive and arteriosclerotic heart disease. It looks to me as if the colon emptied well; they apparently became interested in the cecal area, but I do not believe that they saw anything.

DR. MCKITTRICK: Where is the appendix?

DR. HOLMES: It is retrocecal — an unusual position. There is a tendency for the cecum to contract, possibly because it was somewhat irritated. The cecum is a little high.

DR. MCKITTRICK: As one reads this history it seems too simple. It just cannot be true. I place a great deal of stress on the history in certain conditions. The problem here is, Did this woman have a tumor of the cecum or an inflammatory lesion? If she had a tumor of the cecum, was it carcinoma or lymphoma? If it was inflammatory, was it tuberculosis, a granulomatous tumor such as one gets in regional enteritis or just appendicitis? I do not believe that the patient had carcinoma. Carcinoma gives symptoms that primarily fall roughly into three groups — symptoms because of the anemia that is frequently associated with it, those referable to obstruction and those due to the local inflammatory reaction when the serosal layers are involved. I do not believe that she had a carcinoma a year ago giving symptoms and signs resembling an in-

flammatory lesion in the right lower quadrant with localized tenderness. That, in addition to the absence of evidence of obstructive symptoms, the absence of bowel irregularity and the normal hemoglobin, makes me entirely satisfied to leave carcinoma out of the picture.

I do not know how to bring lymphoma into the picture, or how to rule it out, except that she had no evidence of interference with the mucosal outline. There is nothing one can make out from the x-ray to suggest tumor of the cecum itself, and again the history does not fit into it.

I cannot say that she did not have tuberculosis, however. She had increased lung markings and had had a sister who had died of the disease — in fact, the history does all it can to call our attention to it; but I do not believe she had it.

Here is a woman who had a series of attacks of pain and was well between the attacks, when all the symptoms disappeared. She then had abdominal discomfort localized in the right lower quadrant. Of course that is the picture that we teach students is characteristic of appendicitis. As I read the story and got down to the last attack of several weeks' duration I fully expected to hear about a mass in the right lower quadrant. It apparently was there. Whether or not that was a red herring, I do not know. Chronologically it fitted all right. I thought she had an inflammatory process. If she had an inflammatory process about the best bet is appendicitis. The little appendix stub that Dr. Holmes pointed out fits into the picture perfectly.

She may have had a diverticulum of the cecum with recurrent episodes of discomfort. Although she may have had recurrent episodes of appendicitis during the year before entry, the final attack may have been due to a new disease unassociated with it. But it seems to me that I have to connect up the history of the past year with the story of the findings of this brief admission, particularly when they dovetail into each other all right. I had hoped to be able to give a better differential diagnosis of inflammatory lesions occurring in the right lower quadrant, but to me the only logical diagnosis I can make is appendicitis with an inflammatory reaction — a low-grade appendiceal abscess that we all too frequently see.

DR. JACOB LERMAN: This patient apparently had some form of heart disease, and from the description one has to suspect syphilitic heart disease with aortic regurgitation. She had both diastolic and systolic murmurs with left ventricular enlargement and a normal blood pressure; it could hardly have been due to hypertension so it must have been caused by aortic regurgitation. I should think one would have to tie that in some way.

DR. MCKITTRICK: As I looked at the x-ray films I wondered if it could possibly have been an aneurysm. She had calcification in the aortic knob. She

had, as you say, cardiovascular disease, and I wondered how an aneurysm would fit into the picture. In the first place I do not believe that the history fits it, at least not to my satisfaction. There is no vessel under the cecum that could cause an aneurysm or could cause a mass.

DR. EDWARD HAMLIN, JR.: I should like to hear further discussion of the filling by barium in a chronically or recurrently infected appendix.

DR. MCKITTRICK: I cannot discuss it, but as I looked at the x-ray films, the thin line of barium suggested a nubbin of appendix. How do I know that several centimeters have not sloughed off? When Dr. Holmes showed the film I was not disturbed about it because I thought that fitted into the picture all right.

DR. HOLMES: As a rule, in an appendiceal abscess one does not see the appendix at all, but there are exceptions; I more or less agree with what you say.

DR. ARTHUR W. ALLEN: The man who saw this woman during her attack a year before entry made a diagnosis of appendicitis. Since she was not a good operative risk, he did not take the appendix out at that time. She recovered from that attack down in the country and then had another; since she finally developed a mass that did not go away, he sent her in here.

We also thought that it was appendicitis. So did the X-ray Department. But when we went back over the various cases of appendicitis forming abscess in this region that we had mistaken for tumor, we did not find any with recurrent attacks. All these patients came in with the first episode, when they developed an abscess. We thought that this was inflammatory, since the mass was a little more tender than one would expect with a carcinoma.

We explored the patient under the diagnosis of appendicitis, in spite of the fact that she had had several attacks. When we exposed the area, we could see the whole appendix lying along the lateral wall of the cecum, and palpating through the cecal wall, we easily felt a mushroom-like mass that was about 3 cm. in diameter. We did not disturb it

too much but did an ileotransverse colostomy. Two weeks later we re-explored; the mass had not changed the slightest bit in the interval, which one would expect if it had been an ordinary inflammatory appendicitis. So rather than break into it we took out the right colon. I fear that I spoiled the specimen somewhat, because I wanted to see what it was myself. After taking out the whole mass intact, I eased the appendix off the adherent portion of the cecum. There was a granular area in the wall of the bowel about 2.5 cm. in diameter, but I still did not know the true nature of the process. I thought, however, that it was benign.

CLINICAL DIAGNOSIS

Chronic appendicitis, with abscess formation.

DR. MCKITTRICK'S DIAGNOSIS

Appendicitis, with chronic abscess.

ANATOMICAL DIAGNOSIS

Mucocele of appendix.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: As Dr. Allen implied, when we received the specimen we had a hard time putting the appendix back where it belonged. The proximal 5 cm. of the appendix looked perfectly normal. The serosa was shiny and thin, not at all edematous; but the tip was gone, and in its place we found some fat and inflammatory tissue that apparently belonged on the wall of the cecum, to which it was adherent. Sections showed a great deal of inflammation surrounding large masses of mucus. I believe that the patient had a mucocele of the distal portion of the appendix that apparently had broken but walled itself off. Since it was a retrocecal appendix, it lay against the wall of the cecum and remained there. There was no evidence of carcinoma. Only the distal 2 cm. of the appendix was involved; this is unlike the ordinary mucocele, which begins at the base and produces a balloon-like enlargement of the appendix.

MEDICAL PREPAYMENT-INSURANCE PLANS

AN ITEM published elsewhere in this issue of the *Journal* calls attention to some of the results of a recent survey conducted by the Michigan Health Council, which is composed of the Michigan State Medical Society, the Michigan Hospital Association, the Michigan Medical Service and the Michigan Hospital Service. The survey utilized standard scientific sampling methods to obtain an accurate reflection of public opinion regarding medical matters. The item emphasizes the facts that the people of Michigan have faith in the medical profession, that the majority take advantage of medical-hospital prepayment-insurance plans if they are

available and that medical plans sponsored by physicians are preferable to those offered by insurance companies or to those that might be controlled by governmental agencies.

What applies to Michigan probably represents the attitude of the people of Massachusetts, since the distribution of the inhabitants of the two states according to population density, occupation and income is quite similar. But this must be qualified by the assumptions that the medical prepayment-insurance plan is backed by *all* members of the medical profession, that minor complaints are handled through existing facilities for their adjustment and that the people of Massachusetts are informed concerning the advantages of the Blue Shield.

Many physicians in Massachusetts, particularly specialists, have failed to register as participating physicians with the Blue Shield. A certain number of these object to this inevitable change in the practice of medicine. On the other hand, there are undoubtedly many who refuse because of purely selfish reasons, saying that they "cannot afford to be listed." It is acknowledged that the original fee schedule contained many inconsistencies, which are now in the process of being corrected by groups of specialists, but on the whole, the set fees are reasonable and proper returns for the care of patients whose incomes are sufficiently low to permit them to participate as unlimited subscribers. This opposition on the part of physicians was also experienced in Michigan during the first few years of its medical prepayment-insurance plan, but recently the scheme has received enthusiastic support by the entire profession. Indeed, at the last meeting of the House of Delegates of the Michigan State Medical Society it was unanimously voted that the officers and directors of Michigan Medical Service be commended for their achievement in furnishing several hundred thousand people with medical care on a prepaid basis in a manner that was highly satisfactory to both the patient and the physician and that had resulted in better feeling and understanding between the public and the medical profession.

Another practice that tends to lower confidence is the publicizing of complaints by either subscribers or participating physicians. No plan of

this sort is perfect, particularly in the early days of its existence, but ample facilities have been provided, both in the district societies and in the central organization, for the consideration and ironing out of the difficulties that are sure to arise.

Obviously, a public that is ignorant of the existence of the Blue Shield or of any other medical prepayment-insurance plan cannot be expected to support it. One significant point brought out by the survey of the Michigan Health Council is that three quarters of the people interviewed had never heard of Michigan Medical Service, in spite of the fact that the state has a larger percentage of its inhabitants enrolled in medical-hospital prepayment-insurance plans than has any other state. Such information, of course, must be supplied in Massachusetts either by physicians or by the representatives of the Blue Shield.

The answer to proposals for government-controlled medicine lies in the ability of states or their subdivisions to devise and to consummate plans that aim to correct the deficiencies that are known to exist. The Blue Shield was created by the Massachusetts Medical Society for this very purpose, and all members of the Society should do their utmost to ensure its success.

VITAMINS AND GRAY HAIR

IN THE field of vitamins there has sometimes been a tendency in this country for clinical exploitation of the results of laboratory investigations before those findings have been adequately substantiated, and long before their full import and applicability have been ascertained. This has been particularly true in the treatment of conditions in which the evaluation of the results is partly or wholly subjective. One recent outstanding example has been the widely publicized use first of para-aminobenzoic acid and then of pantothenic acid, either alone or in combination with para-aminobenzoic acid, for the restoration of the original dark color of graying hair in man.

Perhaps the earliest experimental production of achromotrichia was by Oettel,¹ who in the course of studies on the toxicity of hydroquinone observed the graying of the fur of cats. Martin and Ans-

bacher² several years later confirmed these observations and succeeded in producing achromotrichia in mice that could be cured by the feeding of rice-polish concentrate or of small amounts of para-aminobenzoic acid. They believed that the latter was a factor in the vitamin B complex. Ansbacher³ also claimed that para-aminobenzoic acid was a vitamin essential for the growth of chicks and that it was also required by rats for growth and for the maintenance of normal fur. In the rat it has since been shown that a deficiency of pantothenic acid causes poor growth, dermatitis, adrenal hemorrhages and graying hair.⁴ There is reason to believe, however, that achromotrichia is probably a multiple deficiency of para-aminobenzoic acid, pantothenic acid and inositol and that there are certain interrelations between these substances and perhaps others as well.

In the course of studies on the action of sulfonamides, Woods⁵ showed that certain yeast extracts contained a substance that prevented the action of sulfanilamide, and his studies indicated that the action could be duplicated by para-aminobenzoic acid. It was therefore postulated that para-aminobenzoic acid is an essential metabolite in the growth of bacteria. Thus, the action of sulfonamides may be explained on the basis of a competition with para-aminobenzoic acid, the chemical structure of which is quite similar. When the latter is replaced by a sulfonamide, subsequent metabolic activities necessary for the growth and multiplication of bacteria are stopped.⁶

All these findings in themselves are of considerable interest, but they do not necessarily indicate clinical therapeutic applications. In the case of the sulfonamide-inhibitory action of para-aminobenzoic acid, substances supposedly the same or related to the latter are present in exudates and in tissue juices and they, too, tend to prevent sulfonamide action. On the other hand, para-aminobenzoic acid has been found to have no effect either in preventing or in curing some of the toxic effects of the sulfonamides, such as drug fevers and rashes.⁷ Another important aspect of the application of para-aminobenzoic acid in human therapy that is not adequately taken into account by some of those who advocate its use, particularly in small and infrequent doses, is the

fact that this substance, as well as pantothenic acid, is completely and rapidly eliminated from the body, there being practically no storage.⁸ Thus, in a clinical trial of its effectiveness in the treatment of typhus fever,⁹ the doses used every two hours were from five to twenty times the daily doses advocated for the patient with gray hair.¹⁰ Furthermore, when given for long periods and in quantities adequate to maintain significant concentrations in the blood, the possibility of toxic reactions similar to those resulting from sulfonamides or from thiouracil may be anticipated.

Because of the interest aroused by the reports of the effect of calcium pantothenate and para-aminobenzoic acid on the color of gray hair in human beings, Brandaleone, Main and Steele¹¹ conducted a series of studies designed to clarify the confusion concerning which of these compounds is the more important. Each substance was fed alone and in various combinations with yeast. They found no significant decrease in the gray color of the hair from the use of these substances over a period of six to eight months.

Another concept often ignored by those who enthusiastically advocate the use of vitamin supplements is the great difficulty encountered in attempts to produce specific deficiencies, even in experimental animals. The conditions under which such deficiencies are induced are extremely artificial and require the administration of highly purified diets, often deficient in many substances. In man, specific deficiencies are also extremely difficult to produce or to maintain in those who take anything resembling a normal diet. Furthermore, the addition of vitamins to the normal diet has been shown recently to have no beneficial effect in otherwise healthy individuals.¹²

MASSACHUSETTS MEDICAL SOCIETY

The people have faith in the medical profession. They want medical security, and the majority want the job done through voluntary prepayment health plans sponsored and controlled by the medical profession.

These are the basic conclusions that can be drawn from the results of a recent survey of public opinion in Michigan. The survey was sponsored by the Michigan Health Council and utilized standard scientific sampling methods to obtain an accurate reflection of opinion throughout the state.

Some of the questions and the answers are as follows:

As a group, do you think doctors of medicine are doing a good job for the public?

"Yes," 91.6 per cent; "No," 4.2 per cent; and "Don't know," 4.2 per cent.

In general, what are your "pet peeves" regarding the medical profession?

"Doctors overcharge," 6.5 per cent; "Doctors keep patients waiting," 4.4 per cent; "Doctors are dishonest," 5.6 per cent; "Doctors lack interest in patients," 1.7 per cent, and "No peeves," 81.8 per cent.

Is the medical-hospital plan for employees available where you work? If so, do you belong?

The responses to the latter question were "Yes," 72.6 per cent; "No," 13.9 per cent, and "Don't know," 13.5 per cent.

If you were asked to choose, which would you prefer?

Voluntary prepayment program sponsored by the medical profession. 33.7 per cent.

Government-controlled program. 15.5 per cent.

Regular insurance. 13.4 per cent.

Payment for service at time rendered. 26.6 per cent.

No preference was expressed in 10.8 per cent.

The answers indicate that the people have confidence in physicians, that they have few complaints, that nearly three quarters subscribe to a medical-hospital prepayment insurance if it is available and

that, when they know there is a choice, they prefer a prepayment medical plan sponsored by physicians.

The Blue Shield is the medical prepayment plan in Massachusetts. Nearly 4000 doctors are already participating physicians, but the support of every physician is needed so that a united front can be presented to the people and so that it can be said, "The job will be done and done right by the medical profession itself."

If you are not yet a participating physician in the Blue Shield, join your colleagues who are already pioneering in this rapidly developing movement. Write to the Blue Shield (230 Congress Street, Boston) today for complete information.

TREASURER'S OFFICE

The *New England Journal of Medicine* is sent to all fellows whose dues are fully paid. Fellows who have not paid for the current year by March 1 are automatically dropped from the mailing list. To avoid this, it is urged that all fellows pay their dues by this date. Furthermore, the annual refund to district societies is based on the number of payments received in each district by March 1.

ELIOT HUBBARD, JR., *Treasurer*

DEATHS

BONNEVILLE — Alfred J. Bonneville, M.D., of Hatfield, died January 11. He was in his seventy-fourth year.

Dr. Bonneville received his degree from the Medico-Chirurgical College of Philadelphia in 1911. He was vice-president of the Hampshire District Medical Society in 1920 and president in 1921. He was district supervising censor and counselor of this Society from 1922 to 1945. Last year Dr. Bonneville was cited by Governor Saltonstall for his work in civilian defense. He was on the staff of the Cooley Dickinson Hospital, Northampton, and a fellow of the American Medical Association.

His widow and three sisters survive.

HASLAM — Frank A. Haslam, M.D., of Allston, died December 31. He was in his eighty-third year.

Dr. Haslam received his degree from the Harvard Medical School in 1885.

His widow survives.

RICHARDSON — Chesley A. C. Richardson, M.D., of Somerville, died January 30.

Dr. Richardson received his degree from McGill University, Montreal, in 1904. He was a member of the executive board, chief surgeon and president of the Medical Staff at the Somerville Hospital and a member of the American College of Surgeons.

His widow and a brother survive.

THOMPSON — Charles O. Thompson, M.D., of Boston, died January 29. He was in his eighty-third year.

Dr. Thompson received his degree from Columbia University College of Physicians and Surgeons, New York, in 1889. He was a trustee of the Massachusetts College of Pharmacy and a fellow of the American Medical Association.

His widow, a son and a daughter survive.

MISCELLANY

ANNUAL MEETING OF WASHINGTONIAN HOSPITAL

The Washingtonian Hospital for the Treatment and Prevention of Alcoholism held its annual meeting on Tuesday, January 9, in the hospital building at 41 Waltham Street, Boston.

In his report on the activities of the hospital during the past year the medical director, Dr. Joseph Thimann, said that 1134 alcoholic patients had been treated, an increase of 6.6 per cent over the admissions of the previous year. In a group of about 300 patients who were given treatment beyond routine detoxication (part-time protection, psychotherapy and so forth), 25 selected patients received the conditioned-reflex treatment. Since this plan of therapy was started at the hospital, in February, 1942, 111 patients have undergone such treatment, and successful results (permanent total abstinence) have been obtained in 70 cases (63 per cent).

Following the business meeting of the Corporation, the secretary of the Abstinence Club contrasted the early years in the hospital's history, when little or no treatment was given, with present-day conditions. Dr. Arthur H. Ward, acting chief of the Out-Patient Department, then described the work of his department, stating that psychotherapeutic interviews had been given to 200 outpatients during 1944.

Three new members were elected to the Board of Directors: Mr. Courtenay Guild, who for many years has been a member of the corporation and interested in the work of the hospital; Dr. John E. Gorrell, assistant director of the Massachusetts General Hospital; and Mr. Henry L. Johnson, of Utica, New York. Dr. Hilbert F. Day was re-elected president, Mr. Amos B. Little, treasurer, and Colonel George B. Stebbins, clerk.

ONE HUNDRED YEARS IN THE CONSERVATION OF LIFE

In 1842, a young Quaker named Alpheus Phineas Sharp from Winchester, Virginia, was the first graduate of the Maryland College of Pharmacy. Three years later, or just one hundred years ago, he opened a drugstore at Pratt and Howard streets in Baltimore, a store that was destined to develop into the pharmaceutical and biological laboratories of Sharp and Dohme of today. The store was located in a small two-story brick building, and in the transom over the door he placed a painted piece of glass bearing the words **ALPHEUS PHINEAS SHARP — APOTHECARY**. His stock in trade included the standard household remedies of the day, together with imported perfumes, sponges, combs, chemical glassware and other items carried by the drugstore of a century ago. But he filled prescriptions, too, and it was in this field particularly that his ability and knowledge brought to him the confidence and respect of medical men and his brother pharmacists. The business increased and prospered.

In 1852, a rosy-cheeked boy of fifteen came into the store and asked for a position as apprentice. Mr. Sharp liked the eager energy of the boy and apprenticed him. It was the beginning of a lasting friendship and firm business relation, for the boy was Louis Dohme. He cleaned the store, received instruction from Mr. Sharp, carried Mrs. Sharp's market basket, slept in a back room, ate with the family and between times attended the Maryland College of Pharmacy. His hours were from six in the morning to midnight, and his salary three dollars a week. At the college he studied under Dr. Louis Steiner, who imbued him with the conviction that chemistry was the foundation of good pharmacy. He graduated in 1857 and became senior clerk. In 1860 he was made a partner and the firm name was changed to Sharp and Dohme.

The Civil War, with its requirement of large stores of medical supplies, brought further impetus to the growing business. In 1865 the building next to the store was purchased and the manufacture of an extensive line of pharmaceutical products was begun.

In the meantime, Charles, a younger brother of Louis Dohme, had entered the Maryland College of Pharmacy. He graduated in 1862 and later entered the employ of Sharp

and Dohme. His son, Dr. Alfred R. L. Dohme, later became head of the company and is still a director.

A senior clerk of the Sharp and Dohme store at that time, who later became a nationally known figure in pharmacy, was Charles Caspari, Jr. When he later opened his own store, Alfred R. L. Dohme served an apprenticeship with him, and for many years these two men worked together in determining assay methods of drugs that are still official in the *U. S. Pharmacopoeia*. Dr. Dohme became a member of the Revision Committee in 1891 and remained on it for thirty years.

Both Louis and Charles Dohme were presidents of the Maryland College of Pharmacy, and both Charles and Alfred R. L. Dohme were presidents of the Maryland Pharmaceutical Association and the American Pharmaceutical Association. Louis Dohme was a member of the *U.S.P.* Revision Committee, and Charles the chairman of the Board of Trustees of the *U.S.P.* Convention.

During these early years the company's operations were expanding steadily. Branches were established in New York in 1885, Chicago in 1888, New Orleans in 1890, Atlanta in 1893 and San Francisco in 1898, and in other cities as time went on. Many of the products developed half a century or more ago are still widely used today and with their original brand names. Old-time pharmacists will recall the popularity that greeted the introduction of its instantly soluble hypodermic tablets and gelatin-coated pills.

The history of the Mulford Biological Laboratories is equally interesting. The parent organization, the H. K. Mulford Company, had its origin in one of the oldest drug-stores in Philadelphia, having operated on the same site for about one hundred and twenty-five years. One of the earlier proprietors of this store was Joseph P. Remington, who later became dean of the Philadelphia College of Pharmacy. Another was L. E. Sayre, who later became dean and professor of pharmacy at the University of Kansas.

In 1893 world-wide interest had been aroused by diphtheria antitoxin, a new treatment for diphtheria that was then available only from Europe. The Mulford Company also became interested and established the Mulford Biological Laboratories, which produced diphtheria antitoxin in 1894, the first domestic product to be offered commercially in the United States. This entirely new means of treating diphtheria was an epoch-making event in American medicine. It pioneered the way to the development and use of other biologic products for the prophylactic and therapeutic treatment of disease, which have literally saved hundreds of thousands of lives in this country and abroad.

In 1898, the company began the production of smallpox vaccine and developed many of the processes used today in preparing this product. In the intervening years sufficient vaccine for approximately one hundred million vaccinations has been produced.

The list of biological products either developed or first offered commercially by the Mulford Laboratories is long and impressive.

In the fall of 1929 the businesses of both these makers of fine pharmaceuticals and fine biologicals was combined under the name of Sharp and Dohme. During the past fifteen years the company has registered its greatest growth, more than doubling in scope and size. Over twenty-five hundred persons are employed.

More and more emphasis has been placed on research, a new research building housing a large and well-trained technical staff having been completed in 1943. Some of the more recent developments of the Sharp and Dohme laboratories include many familiar brand names. They also pioneered in the synthesis and study of sulfadiazine and sulfamerazine.

These laboratories also developed the commercial process of lyophilizing biologic products, applicable to certain labile biologicals, particularly dried blood plasma, which has been one of the most important single factors in reducing mortality among American wounded in the present war.

Sharp and Dohme has been so closely identified with the health of the nation since 1845 that its anniversary this year surely can find no better words to describe its activities during that time than "A Century in the Conservation of Life."

TUBERCULOSIS CONTROL IN HOSPITALS

Unsuspecting carriers and spreaders of the tubercle bacillus comprise a numerically small but important minority of the population. Although most general hospitals dislike to re-

ceive known cases of pulmonary tuberculosis for treatment of unrelated conditions, their patients and personnel nevertheless remain under constant threat of tuberculous infection. This condition obtains because simple, adequate measures are not taken by the institution to detect among the employees, staff and persons admitted as patients the presence of unrecognized or unreported tuberculosis. The problem is discussed in a recent paper (Block, R. G. Tuberculosis control in hospitals. *Bull. Nat. Tuberc. A.* 30:321, 1944).

* * *

Few hospitals will accept tuberculosis of the lung as a disease to be treated within their walls except the large public institutions with special facilities for that purpose. Recently private hospitals in Chicago were asked:

Do you admit patients with pulmonary tuberculosis to your hospital for treatment of that disease?

Do you admit patients with known pulmonary tuberculosis to your hospital for treatment of other conditions?

Of the 73 hospitals that replied, 5 answered the first question with "Yes," and 68 with "No"; 25 replied to the second question with "Yes," and 48 with "No" or with comments that amounted to a negative reply. The answers indicated that hospital administrators do not consider the admission of the tuberculous an asset to hospital service. In fact many of them thought this was an attempt to uncover an administrative deficiency.

In a community with sufficient beds available in tuberculosis hospitals this attitude does not hamper phthisiotherapy, although in the past, physicians have been deprived of facilities to hospitalize their patients in this manner. With the increase of surgical treatment this has often proved hampering. In communities with inadequate facilities for the treatment of tuberculosis, failure to exploit all the available space, especially when numbers of general hospital beds were vacant, has seemed unjustified.

Fear of Infection

The reason for this is the fear of infecting nontuberculous patients and hospital personnel housed under the same roof. This precaution might be justified if the refusal could really lead to a hospital atmosphere free of tubercle bacilli, but that is not the case.

In recent years, since we have become aware of obscure tuberculosis, our distrust of a negative history and physical examination has become deep-seated and justified. Again and again, evidence has shown that any hospital may have patients with unknown and open pulmonary tuberculosis in its rooms and wards, however little the ailment for which these persons were admitted may have to do with pulmonary disease.

Routine X-ray Films of Chest

Only universal x-ray examinations of the chest of all patients, regardless of the nature of their complaint, could lead to exclusion of the tuberculous. The University of Chicago Clinics and the affiliated Provident Hospital have x-rayed all clinic admissions for some years with most beneficial results. As a method of avoiding contamination, however, this is only part of the necessary effort. As a means of keeping tuberculosis out of hospitals, pre-admission x-rays would lead to an unnecessary increase in the rejection of patients badly in need of care.

Many patients will always enter hospitals without a previous examination, and they cannot be asked to leave if tuberculosis is discovered. Even if a discharge could be effected without harm to the patients, where should they go for treatment? Tuberculosis hospitals could hardly be expected to engage in the treatment of all extrapulmonary, nontuberculous conditions. Sanatoriums are usually not located or staffed for the purposes of general medicine and surgery. Many communities have no facilities specifically intended for the treatment of patients with tuberculosis.

Danger of Unrecognized Tuberculosis

General hospitals should accept the necessity of housing tuberculous patients. The danger of infection arises from not recognizing their pulmonary infection, as has been the unavoidable fact up to now.

Proper isolation in one wing, floor or section of the building is easily accomplished. At the University of Chicago Clinics this has been done during the past twelve years.

Through knowing who and where our tuberculous patients are we are avoiding the most acute danger of contamination, which always arises where germs are being spread without the knowledge of either the distributor or the recipient.

Staff Examination

Isolation protects the medical and nursing staff and other employees against infection from the patient. To make tuberculosis control in a hospital complete, however, physicians, nurses, attendants and so forth, have to be protected not only from patients but from each other, and patients have to be guarded against infection from members of the personnel.

Nearly fifteen years ago, when the University Clinics introduced x-ray examination of the chest by roentgenograms for all nurses, the supervisor of the operating rooms and the nurse in charge of the sterilizing room for the newborn were found with active tuberculosis. Neither was aware of her condition. Stereoscopic roentgenograms were then made obligatory for all physicians and nurses on taking employment, with re-examinations every year for those on general duty and every three months for the personnel of the tuberculosis division.

General Hospital Personnel

Other personnel were exempt from this routine. About a year later, positive sputum findings began to be reported in patients where no other findings suggested tuberculous infection. The clinical findings in most of these patients suggested upper respiratory or bronchitic involvement. The suggestion that an x-ray examination of the chest of the members of the laboratory staff be made was resented by that staff and rejected by administrative officers.

Eventually, it was found that the laboratory worker in charge of sputum tests, a plump and healthy appearing girl, had extensive cavernous tuberculosis with an almost pure culture of acid-fast bacilli in her sputum. She had contaminated the patients' specimens. The embarrassment of apologizing to the patients in question and of revoking the reports to the health department had a most beneficial effect. Roentgen examination of the chest has since been obligatory for all staff members and hospitals employees and has been gratefully received by almost all of them.

Sincere Effort Needed

Experiences like this may seem extraordinary. The author believes they appear so only because there has been no great drive to uncover tuberculosis in hospital personnel. There can be no cause for the hesitation on the part of the general hospital to put its house in order with regard to tuberculosis other than inertia and the fear of administrative commotion.

A painstaking design and observance of rules governing the diagnosis and isolation of the disease in patients and employees will make it possible with safety to admit tuberculous patients to general hospitals. There is no reason why all this cannot be accomplished by voluntary efforts. It is obvious from our newer experience with tuberculosis that such hospitalization is one of the great necessities to achieve the basic aim of all medical endeavor — the saving of human life.

— Reprinted from *Tuberculosis Abstracts* (January, 1945).

NOTE

The following appointments to the teaching staff at Harvard Medical School have recently been announced: Henry Merton Baker, of Boston (A.B. Washington Missionary College 1918, M.D. College of Medical Evangelists 1922), instructor in psychiatry; Clifton John Bennett, of San Francisco (A.B. University of California 1938, A.M. University of California 1940, M.D. Johns Hopkins University 1943), assistant in surgery; Frances Jones Bonner, of Greensboro, North Carolina (A.B. Bennett College 1939, M.D. Boston University 1943), assistant in neurology; William Charles Bridges, of Tacoma, Washington (S.B. University of Washington 1936, M.D. Yale University 1940), research fellow in medicine; Ellen Brown, of Berkeley, California (A.B. University of California 1934, M.D. University of California 1939), research fellow in physiology and fellow of the Commonwealth Fund; Francis Ferenc Foldes, of Boston (M.D. University of Budapest 1934), assistant in medicine; Lorye Edward Hackworth, of Sheffield, Alabama (S.B. Florence, Alabama, State Teachers College 1936, S.M. University of Alabama 1938, M.D. Harvard University 1943), assistant in surgery; Elena Jacoby

Hoffman, of Santiago, Chile (M.D. University of Freiburg 1928) research fellow in physiology; Francisco Lachnit Hoffmann, of Santiago, Chile (M.D. University of Chile 1928) research fellow in physiology; Albert Aurelius Hornor, of Brookline (A.B. University of Virginia 1907, M.D. Harvard University 1911), instructor in tropical diseases; Lucie Ney Jessner, of Cambridge (Ph.D. University of Frankfurt 1920, M.D. University of Königsberg 1926), instructor in psychiatry; Robert Harris McCarter, of New York City (A.B. Princeton University 1938, M.D. Jefferson Medical School 1942), assistant in psychiatry; Frank Lothar Plachte, of Boston (Ph.D. Boston University 1942, M.D. Harvard University 1943), research fellow in pediatrics; Robert Maurice Ravven, of Waban (A.B. Harvard University 1939, A.M. Harvard University 1940, M.D. Harvard University 1944) assistant in psychiatry; Sidney Seymour Sobin, of the University of Michigan (S.B. University of Michigan 1935, A.M. University of Michigan 1936, Ph.D. University of Michigan 1938, M.D. University of Michigan 1941), research fellow in physiology and fellow of the National Research Council; Malwina Stock, of Boston (M.D. University of Lausanne 1939), assistant in psychiatry; Paul Francis Ware, of Newton Center (A.B. Holy Cross College 1938, M.D. Harvard University 1943), assistant in surgery; James Wendell Watson, of Grand Island, Nebraska (S.B. California Institute of Technology 1939, M.D. University of Pennsylvania 1943), assistant in psychiatry; Louis Weinstein, of Brighton (S.B. Yale University 1928, S.M. Yale University 1930, Ph.D. Yale University 1931, M.D. Boston University 1943), assistant in infectious diseases; Henry Wermer, of Brighton (M.D. University of Vienna 1936), instructor in psychiatry; and James Martin Woodall, of Boston (A.B. Mercer University 1922, M.D. Harvard University 1930), instructor in psychiatry.

BOOK REVIEWS

Radiation and Climatic Therapy of Chronic Pulmonary Diseases: With special reference to natural and artificial heliotherapy, x-ray therapy and climatic therapy of chronic pulmonary diseases and all forms of tuberculosis. Edited by Edgar Mayer, M.D. 8°, cloth, 393 pp., with 46 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$5.00.

This volume was written by twenty-two collaborators and edited by Dr. Edgar Mayer, long a student of light therapy in pulmonary tuberculosis. The book deals with artificial light, solar radiation, climatotherapy, x-ray therapy and, finally, surgical versus conservative treatment of bone and joint tuberculosis. The concluding chapter is a résumé by the editor of the effects of climatic, x-ray and light therapy on chronic pulmonary diseases and all forms of tuberculosis. In the first chapter, the editor states that he incorporated both skeptical and enthusiastic reports, although an attempt was made to appraise both groups quite objectively. He further agrees that, in some chapters, the deductions are based too frequently on clinical impressions and uncontrolled observations. The reviewer keenly appreciates this point, since many problems relating to the biophysics and physiology of radiation are as yet little understood and await further biophysical as well as clinical study.

The chapters covering the physics of light radiation, especially the one on the physiologic action of light, contain a great deal of valuable information and present to the reader up-to-date information on the effects and dangers of light therapy. Sources of light from the sun, the carbon-arc lamp, the quartz mercury-vapor lamp and the cold quartz lamp are adequately discussed from the physical angle, as well as from the point of view of biophysics and therapeutics. X-ray therapy is recommended in some nontuberculous diseases of the chest, such as actinomycosis, carcinoma and unresolved pneumonia; it is considered beneficial in some extrapulmonary forms of tuberculosis, dubious in tracheobronchitis, and dangerous in pulmonary tuberculosis. The influence of the climate and weather on the human organism in health and in disease is considered in detail, as is climatic therapy of nontuberculous chronic pulmonary diseases. Finally, an attempt is made to evaluate surgical versus conservative treatment in bone and joint tuberculosis.

Dr. Mayer has been in the forefront the past two decades as a student of light therapy. The pooling together in one

book of the experiences of twenty-two eminent men in the field of light therapy makes this book a "must" on the library shelves of anyone interested in tuberculosis and chronic pulmonary diseases. Skeptics will find much, as the editor has pointed out, that is unscientific or empiric. Yet, the text, with its many illustrations, contains a large amount of material that is useful and fundamental for an understanding of present-day knowledge concerning these forms of therapy. The book brings into fruition the many years of laboratory and clinical study by the collaborators as well as by the editor. Although it constitutes a summary of a controversial subject, the book adds a welcome chapter to medical literature.

Bacterial Infection: With special reference to dental practice. By J. L. T. Appleton, D.D.S., Sc.D. Third edition, thoroughly revised. 8°, cloth, 498 pp., with 86 engravings and 5 plates. Philadelphia: Lea and Febiger, 1944. \$7.00.

This is a real textbook of dental bacteriology. The author lays out the broad general basis of bacteriology and immunology in the early chapters, drawing abundant example and application from dental theory and practice. It is therefore hardly a text for teachers who give dental students a course in general medical bacteriology and then leave to uncritical clinicians the special application.

As the title implies, much of the subject matter consists of a discussion of infection and the factors affecting its occurrence. The author's discussions are brief and pointed, with references to more extended reading for the unconvinced. Unfortunately, the references themselves are not always convincing.

If courses could be radically revised as soon as a vital new text appears, this book would gain quick acceptance as a text. Until then it will serve as a useful and stimulating source-book and one whose usefulness is not limited to the dental bacteriologist.

Infections of the Peritoneum. By Bernhard Steinberg, M.D. With a foreword by Frederick A. Coller, M.D. 8°, cloth 455 pp., with 45 illustrations and 21 tables. New York: Paul B. Hoeber, Incorporated, 1944. \$8.00.

This book, which "it is hoped will be read by the practitioner," will find, nevertheless, a more sympathetic understanding among those in the vanguard of scientific progress. Although the subject is comprehensively dealt with, the special feature of this volume is the presentation of data gathered over many years from the author's own research efforts.

The evidence deduced by the author from these data may be summarized briefly as follows: Peritonitis is a rapidly diffusing infection of the peritoneal cavity in which the exudate obtained by needle puncture is of considerable diagnostic and prognostic value. In the early stage, the average oil-immersion field shows none to 6 free bacteria, whereas the small to moderate number (average, 4000 per cubic millimeter) of neutrophilic polymorphonuclear leukocytes, which make up 85 to 90 per cent of the cells, contain 1 to 10 ingested bacteria, usually of a single species. In the moderately advanced stage, these leukocytes increase to from 60,000 to 250,000 cells per cubic millimeter, the number of free bacteria increases, and a mixed flora may be present. In the late stage, exfoliated mesothelial cells, many of which are degenerated, increase, often to 20 per cent of the cell count; the polymorphonuclears show a high proportion of stab forms and contain many phagocytosed bacteria; the leukocytes decrease in number, many being degenerated; and 10 or more bacteria, almost always more than one species, are seen free in each oil-immersion field. The quality of the defense is reflected in the richness of leukocytic mobilization, the freedom of the leukocytes from degenerative changes, the effectiveness of the phagocytosis of bacteria, the absence of red cells and the relative absence of mesothelial cells. Virulence of the organism and resistance by the host alter these features in varying directions. The safety of needle puncture is stressed and its value in diagnosis will not be disputed by anyone who has had some experience with it in doubtful cases.

The second specific contribution discussed in this volume is the intraperitoneal administration of "coli-bactragen." This is a mixture of a specially prepared colon-bacillus vaccine, aleuronat and gum tragacanth in salt solution and is recommended for mobilization of the polymorphonuclear leukocytes

in the early stages of peritonitis and as a prophylactic against peritonitis in bowel surgery. The clinical evidence for the therapeutic virtues of coli-bactragen is not extensive enough to be convincing, and the author is duly cautious in his claims for its value.

Many interesting experimental data are presented on the peritoneal defense against infection and the value of various therapeutic agents, such as morphine, pituitary extracts and posture. The conclusions reached on the whole reflect the principles guiding surgeons whose therapy is based on critical appraisal of the scientific evidence. Exception may be taken to the impression left by the author that antisera for colon-bacillus and gas-bacillus infections have a demonstrated clinical therapeutic value. Exception may also be taken to the author's interpretation that statistical evidence does not prove the usefulness of sulfonamides in abdominal surgery (penicillin is not mentioned).

One encounters statements of doubtful validity here and there: "The serum protein becomes concentrated as a result of greater nitrogen catabolism" (page 77); "For the duration of the first few days of peritonitis morphine sulphate will control pain and intestinal distention" (page 214) (there is no good evidence that morphine will control distention); "The incidence of pulmonary complications can be reduced appreciably by frequent inhalations of carbon dioxide" (page 214) (the value of carbon dioxide for this purpose has not been demonstrated, and its use has been abandoned by clinics that were among the first to recommend it). On page 241 the author recommends coli-bactragen in conjunction with the operative treatment of gonorrheal peritonitis; this implies that operative treatment has a place in the therapy of such cases, which is not generally accepted. The author's discussion of shock reflects the widespread fallacy that hemoconcentration is a characteristic feature of shock (it should be evident that hemoconcentration is present in burns and other states in which plasma loss predominates but not in conditions in which whole blood is lost, for example, in hemorrhage, or in which no blood is lost, for example, severe generalized infections).

There is much that is repetitious in this volume, but the reviewer believes that this and a tendency to prolixity are defects that a further edition could remedy. Perhaps the author, having in mind the student and the immature practitioner, may regard such criticism as irrelevant. In any case, the book has considerable merit, not the least of which is a splendid and comprehensive bibliography following each chapter.

Physical Medicine in General Practice. By William Bierman, M.D. 8°, cloth, 654 pp., with 310 illustrations and frontispiece. New York: Paul B. Hoeber, Incorporated, 1944. \$7.50.

The Government has rationed food, clothes and transportation but not words. Rationing of the last was left for the author of this book. Dr. Bierman's concise style of writing and his economy of words stood him in good stead in producing the present volume. In a relatively limited space he has covered practically the entire field of physical medicine. The thoroughness that characterized his previous works, in which he dealt with single subdivisions of this subject, such as fever therapy and short-wave current, has been retained in a measure in this more general book. It is regrettable, however, that electrophysics is not treated so consummately as are the physiologic effects produced by the various physical measures. By way of an illustration, a brief discussion of such a basic matter as the electron theory of matter and the relation of electricity and magnetism, which forms the basis of induction, is omitted. Nor is it clear why he saw fit to treat the testing the neuromuscular units for the reaction of degeneration and the sinusoidal and faradic currents, as well as static electricity, under the main heading of "Galvanic Current." But these points are of minor importance and will probably be corrected in subsequent editions, which will undoubtedly be numerous, since the text as a whole is meritorious.

The book covers the usual subjects that are treated in similar works, such as, thermotherapy, phototherapy, electrotherapy, hydrotherapy and electrodiagnosis. In addition it contains chapters on massage, exercise and occupational therapy, subjects with which the general practitioner, as a rule, is not sufficiently familiar to derive from them the great advantage that they offer in the treatment of numerous injuries and certain forms of paralysis.

The final quarter of the book, which is devoted to a discussion of the treatment of specific diseases commonly affecting the systems and structures of the body, will be of inestimable help to the general practitioner provided he has familiarized himself with the preceding chapters, which treat the fundamentals of physical medicine.

Numerous detailed drawings and an appendix covering specifications for physical-therapy equipment are additional features of value.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Segmental Neuralgia in Painful Syndromes. By Bernard Judovich, M.D., instructor in neurology, Graduate School of Medicine, University of Pennsylvania, clinical instructor in neurology, Women's Medical College, and chief of Neuralgia Clinics, Philadelphia General Hospital, Graduate Hospital, and Women's Medical College Hospital, Philadelphia; and William Bates, M.D., professor of surgery, Graduate School of Medicine, University of Pennsylvania, consulting surgeon, Babies' Hospital and Philadelphia Home for Incurables, and consulting general surgeon, Wills Hospital, Philadelphia. With a foreword by Joseph C. Yaskin, M.D., professor of neurology, Graduate School of Medicine, University of Pennsylvania, Philadelphia. 8°, cloth, 320 pp., with 178 illustrations. Philadelphia: F. A. Davis Company, 1944. \$5.00.

This monograph on a subject formerly known as intercostal neuralgia emphasizes the clinical and therapeutic aspects of segmental syndromes. The clinical value of tenderness is stressed, and much space is devoted to therapy, especially the technic of nerve infiltration. Abdominal-wall neuralgias and other conditions often mistaken for visceral organic disease are thoroughly discussed. Current literature has not been utilized in the writing of this monograph, but it is well illustrated and a number of case histories are inserted in the text.

Artificial Pneumothorax in Pulmonary Tuberculosis, Including Its Relationship to the Broader Aspects of Collapse Therapy. By T. N. Rafferty, M.D., with an introduction by Henry S. Willis, M.D., superintendent and medical director, William H. Maybury Sanatorium, Northville, Michigan. 8°, cloth, 192 pp., with 26 illustrations and 14 tables. New York: Grune and Stratton, 1944. \$4.00.

The purpose of this monograph is to compare and evaluate existing standpoints and practices in the use of artificial pneumothorax in the treatment of pulmonary tuberculosis. The book is divided into three parts: general considerations, the choice of cases and management of the procedure.

Technic of Electrotherapy and Its Physical and Physiological Basis. By Stafford L. Osborne, M.S., Ph.D., assistant professor, Department of Physical Therapy, Northwestern University Medical School; and Harold J. Holmquest, B.S., B.S. (M.E.), lecturer in applied physics, Department of Physical Therapy, Northwestern University Medical School. 8°, cloth, 780 pp., with 240 illustrations and 72 tables. Springfield, Illinois: Charles C Thomas, 1944. \$7.50.

This textbook is intended to provide a sound physical and physiologic rationale for the technic and application of electrotherapy; it is not intended to replace clinical textbooks but should be used to supplement such treatises. The work is based on lectures given for the past sixteen years at Northwestern University Medical School. The subject matter is divided into four parts: effects and technical application of direct current; electrical muscle stimulation; radiation; and high-frequency currents. The book is well documented and printed in a good type.

The Neurosurgical Patient: His problems of diagnosis and care. By Carl W. Rand, M.D., clinical professor of neurological surgery, University of Southern California School of Medi-

cine. 8°, cloth, 576 pp., with 121 illustrations. Springfield, Illinois: Charles C Thomas, 1944. \$4.00.

This new book is based on clinical discussions with students of the neurosurgical department of the Los Angeles County General Hospital, where medical students are assigned cases for review. The discussions are given in a conversational rather than textbook style, and complicated technical terms have been avoided. Informal clinics on fifty-four different subjects are presented in four sections: the spine, head injuries, the brain and miscellaneous conditions.

The Pathogenesis of Tuberculosis. By Arnold R. Rich, M.D., associate professor of pathology, Johns Hopkins University School of Medicine. 4°, cloth, 1008 pp., with 89 illustrations, 20 tables and 4 charts. Springfield, Illinois: Charles C Thomas, 1944. \$10.50.

This important new book presents the basic factors and principles that influence the occurrence of tuberculous infection or determine its progression or arrest. The work is well documented, and a list of 1417 selected references is appended to the text. The book is well printed, with a good legible type on good paper.

Rebel Without a Cause: The hypnoanalysis of a criminal psychopath. By Robert M. Lindner, Ph.D., United States Public Health Service (R), psychologist, United States Penitentiary, Lewisburg, Pennsylvania, and lecturer in criminology, Bucknell University. With an introduction by Sheldon Glueck, LL.B., Ph.D., professor of criminal law and criminology, Law School, Harvard University, and Eleanor T. Glueck, Ed.D., research criminologist, Law School, Harvard University. 8°, cloth, 296 pp. New York City: Grune and Stratton, 1944. \$4.00.

This volume portrays the basic characterologic factors in the life of a young criminal and reconstructs the mental history of an abnormal personality from earliest infancy through a perverted law-breaking boyhood to young manhood in a penitentiary environment, as revealed through a combined technic of psychoanalysis and hypnosis.

Lippincott's Quick Reference Book for Medicine and Surgery: A clinical, diagnostic and therapeutic digest of general medicine, surgery and the specialties, compiled systematically from modern literature. By George E. Rehberger, M.D. Twelfth edition. 4°, cloth, 1460 pp., with 305 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$15.00.

This standard reference work, first published in 1920, has been thoroughly revised and brought up to date. The sections on gynecology and genitourinary diseases have been entirely rewritten. The list of drugs has been revised in accordance with the twelfth revision of the *United States Pharmacopeia* and the seventh edition of the *National Formulary*. The book is divided into eleven parts, dealing with different fields of medicine, and each disease or disorder is arranged alphabetically and is described clinically, its diagnosis, etiology, prognosis and treatment being considered in this order. All material is made available through a comprehensive index. This volume should prove valuable as a ready reference work for the general practitioner.

NOTICES

BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held in the Main Lecture Room of the Harvard Biological Laboratories on Wednesday, February 21, at 8 p.m.

PROGRAM

A Study of Fibrin with Acid and Basic Dyes. Drs. M. Singer and P. R. Morrison.

Use of Stains in Electron-Microscope Investigation of Protein Structure. Miss M. A. Jakus.

Double Refraction of Flow as a Method for Studying Long Molecules. Dr. J. T. Edsall.

Some Recent Advances in Radioactive Tracer Technics. Dr. R. D. Evans.

THE HERNIATED INTERVERTEBRAL DISK*

An Analysis of 400 Verified Cases

JAMES L. POPPEN, M.D.†

BOSTON

IN THE last ten years considerable material has appeared in publications indicating that the presence of herniated intervertebral disks is not a myth but a proved entity, producing a train of symptoms and signs that are as characteristic as are those of renal colic or appendicitis. As is so true of all new developments, there are always those who are overenthusiastic in the treatment of this disease and those who are skeptical about it.

It is astounding to find that so many proved ruptured disks have been discovered in such a comparatively short time. Inasmuch as it is known that this condition was present since man first assumed the upright position, and that many patients with the now characteristic group of symptoms of a herniated disk did quite well on conservative measures, one must wonder whether or not much of the surgical interference that is now instituted may not be superfluous or even unjustifiable. It is with this in mind that 400 operatively proved cases, in which eighteen months to ten years have elapsed since surgical intervention, have been studied.

An interpretation of one's results cannot be entirely unbiased, and what one surgeon would consider a good result may be judged a poor result by another. All factors must be weighed carefully, such as the personal factor, — the surgeon, industrial surgeon and employee, — the discomfort and disability of the patient before operation as compared with his postoperative symptoms, the ability of the patient to carry out his usual occupation, and his wage-earning capacity. This survey was made on the assumption that most patients are honest, and therefore considerable reliance was placed on the patient's statements whether they considered the results satisfactory. If, however, a patient thought that the result was satisfactory but the facts indicated that he was not back at his usual occupation because doing so resulted in considerable low-back discomfort and necessitated frequent absence from

work, this result was certainly not satisfactory from the industrial surgeon's or employer's standpoint. The patients were checked personally, but they were also requested to answer a questionnaire that gave additional information. In this manner it could be determined with reasonable accuracy whether the operative procedures instituted were justifiable in each case.

There can no longer be any skepticism concerning the presence of the herniated disk and its actual participation in the production of low-back pain and sciatica. There is, however, no question that the time and type of treatment to be instituted are still somewhat vague. For this reason one must not be too decided in his opinion about the proper treatment in a given case until a thorough history has been taken and a complete physical examination, including a bone and joint as well as a neurologic survey, has been made. The laboratory studies should include the usual blood and urine examinations, and roentgenograms of the lower spine and sacrum should be made. These studies usually rule out the more frequent causes of low-back pain with sciatica, such as osteoarthritis, metastatic malignant bone lesions, angiomas of the bone, osteomyelitis, old compressed fractures, Marie Strümpell arthritis, diabetic neuritis, syphilis, and postherpetic neuralgia — evidenced by segmental scars on the skin.

Spinograms should not be used in every case. Certainly, if all the studies have been normal, in the presence of a typical history of a herniated disk as well as typical neurologic findings, it is usually safe to carry out an exploratory operation. Roentgenograms with a contrast medium (oxygen is used exclusively at the Lahey Clinic) should emphatically be made, however, in the following four types of case. The first group comprises patients who have severe sciatica that has not responded to conservative measures in three weeks. If a large defect is present, an exploratory operation is indicated. If a small or no defect is present, one may justifiably continue conservative measures. The second group includes those in whom either the history or the

*From the Department of Neurosurgery, Lahey Clinic.

†Neurosurgeon, Lahey Clinic.

findings are atypical. The third group is comprised of patients with low-back pain in whom a fusion is contemplated, unless exploration is to be carried out at the time of fusion. The fourth group is formed of patients in whom roentgenograms of the lumbar spine show marked degenerating changes with spur formation.

The study of the 400 cases was instructive because of the fact that the histories were uniformly characteristic. The physical findings varied considerably, depending entirely on the time the patient was examined and whether the condition was in an acute, subsiding or quiescent state. During the quiescent stage the findings in many cases were absolutely normal. Since, therefore, the patients were examined in varying stages, the percentages quoted in the findings must necessarily be different than would be the case if every patient had been examined only during the acute stage.

CLINICAL DATA

Frequency

This series represents 8 per cent of the patients who entered the clinic with the outstanding complaint of low-back pain, with or without sciatica. This emphasizes the point that even though the herniated disk is an important link in the chain of conditions that cause low-back pain and sciatica, it is by no means the predominant one.

Etiology

It is of interest that 7 patients belonged to families several members of which had had herniated disks. In one family there were two sisters and one brother; in another, two brothers and sisters. A history of injury was given in 65 per cent of the cases. It is significant that the usual account of injury was that of a sudden lifting strain during which the patient felt a snap in the low back and immediately experienced either a numbness and tingling in one leg or a sudden, severe, sharp pain. In many cases, however, the paresthesia or pain did not come on until several hours or days later. It is somewhat difficult to explain why ruptured cartilages do not follow severe injuries such as compression fractures or dislocated fractures of the spine. It appears that actual rupture may take place into the crushed bodies rather than posteriorly, and that during the period of convalescence actual bony union takes place, incorporating the injured disk, and in that manner prevents later herniation.

There can be little question that rupture of disks occurs most frequently at the site of greatest mechanical stress and strain in both the cervical and lumbar regions. The fact that 68 per cent of the cases occurred in males and 32 per cent in females also tends to favor trauma, especially since 84 per cent of the cases occurred in patients between the ages of twenty and fifty and about equally divided in these three decades. Sixty-five per cent were

manual laborers and 35 per cent professional workers. In only 6 per cent of the patients were there demonstrable anomalies, such as spina bifida occulta. Abnormally placed facets were frequent.

Subjective Symptoms

The duration of symptoms varied greatly. There was no accurate way of determining the actual time element, since in all the cases the symptoms tended to occur periodically, lasting from a few days to several months and occurring over a period of up to twenty years.

Recurrent low-back pain was present in 95 per cent of the patients. It preceded the sciatica in many cases and appeared simultaneously with the leg pain in the remainder, in some cases being located one or two vertebrae higher than the herniated disk. Sciatica was present in every case except 2, in which there was severe mid-low-back pain, coming on at intervals. Both patients proved to have midline ruptures without compression on separate nerve roots.

In 63 per cent of the patients the sciatica was unilateral. It must be emphasized that the pain must be in the sciatic distribution if the disk is at the fourth or fifth lumbar segment, and any pain that is not limited to it must be viewed with skepticism in the diagnosis of herniated disk. Nine patients had pain in the thigh due to herniated disks at the second or third lumbar segment. The exceptions to the rule hold true, however, and in this series 5 patients had associated severe pain in the inguinal region. Seventy-five per cent of the patients complained of pressure paresthesia. Minor motor changes were noted in many cases. Paralysis, however, was the chief complaint of 6 patients. Fifty-two per cent of the patients complained of radiating pain into the leg on coughing or sneezing. Constipation was present in 47 per cent of the series, probably because straining at stool accentuated the leg discomfort. The fact that patients with herniated disks are usually more comfortable while lying down is important to remember, in contradistinction to those with cauda equina tumor, in whom pain is usually less in the upright position.

Objective Findings

The most constant objective finding was a positive straight-leg reaction, which was present in 90 per cent of the patients when the protrusion was at the third, fourth or fifth lumbar segment. It is safe to say that this test would be positive in nearly 100 per cent of patients if they were examined during an acute phase of the condition. Certainly, if a patient is in a supposedly acute phase and a positive straight-leg reaction is not present, other pathologic factors should be suspected.

Seventy-five per cent of the patients demonstrated definite spasm of the low-back muscles. Localized paraspinal tenderness was present in

80 per cent. Forty-eight per cent had sensory changes in the fifth lumbar or first sacral dermatomes or both. In 35 per cent, list of the spine occurred away from the site of the lesion. In 45 per cent, atrophy of muscle groups — gluteal or calf — or of the extremity from disuse was noted. Fibrillary twitchings were present in 25 per cent. An absent Achilles reflex was noted in 43 per cent, being most frequent with herniated disks at the fifth lumbar segment.

The spinal-fluid studies showed an elevated total protein in only 53 per cent of the patients. Evidence of spinal-fluid block was found in only 2 per cent of the cases. This may be accounted for partly by the fact that in the early group the lumbar puncture was always made in the fifth lumbar space, whereas it is now usually made in the third lumbar space.

Roentgenograms of the lumbosacral spine demonstrated a narrowed interspace at the site of the disk in 15 per cent of the series, localized arthritis (possibly traumatic) in 20 per cent, and an unstable lumbosacral joint in 11 per cent. No characteristic finding indicating a herniated disk was noted in the routine roentgenograms of the spine. Narrowing of the disk space was not an assurance that a posterior dislocation of a disk was present. From these experiences, a normal roentgenogram of the low spine in the presence of a typical history and findings is an additional indication of the probable presence of a ruptured cartilage.

Potentially unstable lumbosacral joints — abnormally placed facets — were present in 6 per cent of the cases. Congenital defects, such as spina bifida, occurred in 6 per cent, indicating at least that congenital malformation demonstrable roentgenologically was not an important factor in producing ruptured cartilages.

Treatment

The best treatment of herniated disks will remain a subject of debate for some years to come. Conservative surgeons will continue to treat patients much along the same lines as they have treated them in the past — by physiotherapy, immobilization, traction, epidural injections, manipulations and so on. The enthusiasts will, of course, operate on all patients who have symptoms. There are also those who will try to maintain a middle course, attempting to determine which patient should be treated conservatively, which should have simple removal of the disk, and which require a combined removal of the ruptured cartilage and fusion. It is the latter course that would be ideal. The only disadvantage about this position is that with the present knowledge there is no definite rule by which the proper treatment in each case can be determined, and there will not be until at least ten to fifteen years have elapsed so that the results of treatment can be adequately compared. Sufficient time has

elapsed and an adequate number of patients have been treated, however, so that at least certain facts can be kept in mind when the decision concerning treatment is considered.

There is no question that operative procedures were instituted in some cases reported in this series in which conservative measures would have adequately taken care of the situation, but in no case was the condition made worse, except temporarily by postoperative discomfort. Certainly, one should consider the tolerance for pain and the disability of each patient, to decide whether the situation in all its details and findings is typical or atypical, and to make use of these interpretations in deciding on the form of treatment.

Any patient who has had repeated disabling attacks of sciatica necessitating narcotics and who in the previous few months has been unable to work because of a ruptured cartilage should, in my judgment, have operation. When a patient has had mild recurrences of symptoms causing considerable discomfort but not severe enough to discontinue work at any time, he should just as certainly, in my opinion, be treated conservatively. In the latter case, if the neurologic examination shows considerable evidence of root compression, even though the pain is not severe, the patient should have the benefit of surgery.

In any patient who has been disabled with severe pain only for one or two days out of the year, and between attacks is normal, conservative treatment is justified. By conservative measures is meant physiotherapy in the form of heat, massage and postural exercises, rest in bed on a firm mattress and administration of large doses of Betaxin intravenously for a few days. Betaxin is given in an attempt to relieve the associated mechanical radiculitis. Infiltration with procaine locally into the muscle is also of value.

When operation seems indicated, the question naturally arises whether fusion should be carried out at the time the disk is removed. It seems logical that any patient with predominating leg pain (sciatica) and with minor back difficulty whose roentgenograms show no bone changes should have only the disk removed if this is done through a small exposure, whereas in a patient who has predominating back pain, with definitely abnormal facets and evidence of an unstable back, and who has to do hard manual labor, removal of the degenerated cartilage with fusion is indicated. With the latter state, the long initial hospital stay and inability to work may finally prove to be a shorter course in obtaining relief than would have been the case if the disk alone had been removed.

Adequate removal of all the degenerated cartilage should be done in all patients operated on for herniated disk. It is not sufficient to remove only the loose, fragmented portions.

Postoperative Course

The immediate postoperative course of the patient operated on for a herniated disk is usually smooth, the patient being allowed any liberty he wishes to take. There is no objection to having him stand beside the bed to urinate any time after he has recovered from the anesthetic agent. The back rest is adjusted to any position in which the patient is most comfortable. He is usually up on the seventh postoperative day. The time of getting out of bed after an operation for herniated disk is best left in some degree to the judgment of the patient. Some patients have considerably more discomfort than others and for varying lengths of time after operation. The most annoying postoperative symptoms that occurred in this series were severe spasms of pain in the low back, involving the muscles of the thighs as well. These spasms frequently come on at night, lasting for several minutes and occurring three or four times during the night. They are controlled only by fairly large doses of narcotics. These pains usually occur on the fourth to the seventh postoperative day and last for several days. In 1 case they lasted for several weeks. The incision was reopened in 2 of 10 cases in which these spasms of pain occurred, but nothing was found to account for them except local postoperative swelling of tissue.

Infection occurred in 3 patients. Opening the incision widely and allowing adequate drainage as soon as the infection was noted, with liberal use of the sulfonamide drugs, brought about wound healing in a few days.

The shortest postoperative stay in the hospital was four days and the longest five weeks; the average stay was twelve days.

Late Results

The late results are analyzed in Table 1.

The relief of sciatica was satisfactory in most of the cases. Residual back discomfort on heavy lifting or sitting in a cramped position for many hours

TABLE 1. Analysis of Late Results.

LATE RESULT	PERCENTAGE OF SERIES
Relief of pain:	
Complete relief of pain	65
Complete reduction in sciatica	90
Reduction in symptoms:	
75 to 90 per cent	20
50 to 75 per cent	10
No relief	5
Return to usual activity:	
Returned in 1 to 3 months	30
Returned in 3 to 6 months	30
Returned in 6 to 12 months	35
No return	5
Unable to do heavy lifting without low-back discomfort	60
Able to do everything without discomfort	38
Complaint of low-back discomfort when tired	40

occurred in almost half the patients. This percentage was not materially altered in those who had also had fusions, who comprised 9 per cent of the series. It must be admitted that of the patients

in whom fusion was performed the predominant symptom was low-back pain, even though associated with sciatica, and that the roentgenograms showed unstable facets with localized reaction at the level of the ruptured cartilage. Two patients complained of severe occurrences of low-back pain in whom spinograms demonstrated midline protrusions at the fourth lumbar space that were verified by exploration. Even though only low-back pain was complained of with no associated sciatica, simple removal of the ruptured cartilage was performed. One patient was completely relieved; the other has had no further severe pain necessitating bed rest, but has been unable to carry on his usual work in a foundry because of low-back discomfort.

The ability to return to work in their usual capacity is encouraging to these patients. This ability depends to some degree on the information that the patient is given before the operation. It must be made clear to him that just because he has had an operation on his back does not mean that it has been weakened and therefore he must be careful of it. Co-operation between the employer, surgeon and patient is highly important. It seems unwise to ask the patient to do a full day's work the day he reports for duty. One must keep in mind that these patients have not used the muscles that are ordinarily exercised in their work and therefore have to be gradually conditioned, just as in any athletic sport in which different groups of unconditioned muscles must be built up gradually. Permanent damage, both physical and mental, can be done by unintelligent conditioning by either the patient or the employer. For this reason postural exercises and physiotherapy are extremely important parts of the postoperative care.

In 15 per cent of the series the patients did not obtain relief; in the majority of cases this was not the result of recurrence. All patients who have persistent leg pain, however, must be suspected of having either a recurrence in the same space or another disk rupture above or below the space where the ruptured cartilage was removed, or a persistent radiculitis. In a few patients posterior spur formation — so-called "eagle-beaking" — of bone from localized degenerative changes takes place, and if the nerve is not adequately decompressed, persistent leg pain will remain.

COMPLICATIONS

In discussion of this subject emphasis has been placed on the complications that may result from surgery. In competent hands, however, no serious sequelae should follow operation. There were no deaths or paralysis in any of the patients operated on in this series, even though in several cases a root segment was intentionally sacrificed in an attempt to relieve pain. In 1 case injury was unintentional. There were no demonstrable alterations

except slight sensory changes in the lateral aspect of the foot and inability to spread the small toes.

It is important to emphasize what may happen if a patient who has a large ruptured cartilage remains untreated or is treated by nonsurgical methods. In replying to patients who inquired what would happen if operation was not undertaken, it was my original policy to say that so far as I knew, nothing would happen except that the periodic attacks of pain and incapacitation for work would persist for varying periods of time; that, after all, herniated disks had been present for many years in many cases, even though unrecognized except when causing paralysis; and that the present method of proving their presence and taking care of them had been in use only in the last decade. This advice and the logic back of it were unjustifiable, as indicated by the fact that in 6 cases in this series sudden complete paraplegia developed as a result of ruptured cartilage. Of these patients, 2 who had previously always been relieved by careful manipulation by competent osteopaths developed the paraplegia immediately following manipulation; 2 were manipulated by highly competent bone and joint surgeons

and were paralyzed when they awakened from the anesthesia; 1 made a sudden misstep and developed an immediate cauda equina-paralysis syndrome; and 1 gradually developed a cauda equina-tumor syndrome with complete paralysis. In the last case, operation revealed a large disk with an associated adhesive arachnoiditis that completely obliterated the lumbar canal. Even though the protruded cartilages were removed in a relatively short time following the paralysis, many weeks and months elapsed before complete function returned. In 2 of these 6 patients five years after removal of the herniated disk, there is still a marked residual that prevents normal activity.

SUMMARY*

Four hundred proved cases of ruptured intervertebral disk in one or more spaces have been analyzed on the basis of objective and subjective symptoms, and the results eighteen months to ten years after operation have been presented. Hence, no reference to the literature has been made.

605 Commonwealth Avenue

*This article comprises an analysis of a series of cases seen in a single clinic over the course of ten years and comparative opinions concerning diagnosis and treatment have purposely not been discussed.

CARDIAC FAILURE ASSOCIATED WITH ACUTE ANEMIA

THOMAS D. KINNEY, M.D.,* AND G. KENNETH MALLORY, M.D.†

BOSTON

IT HAS long been known that anemia has a profound effect on the heart. In 1857, Bamberger¹ pointed out that cardiac enlargement was found in many patients suffering from chronic anemia, a finding that has since been confirmed by many observers. In 1931, Ball,² for the first time, demonstrated such enlargement by x-ray and showed that the diameter of the heart returned to within normal limits after the anemia had improved. This finding also has been confirmed by other investigators.^{3, 4} In 1939, Ellis and Faulkner⁵ studied the hearts of 64 patients suffering from anemia. Of 38 cases examined by x-ray, 20 showed cardiac enlargement, and of 26 that were followed, 18 showed a decrease in the heart size with improvement of the hemoglobin level. It was also found that the anemia tended to produce a lowering of the systolic and diastolic blood pressures. Electrocardiographic studies were carried out. Of 29 patients who were followed, 7 showed abnormal records; in 5 cases these became normal as the blood level increased. With one exception the abnormal records were consistent in that a depression of the ST segment and a flattening or inversion of the T waves in Lead 1 or in Leads

1 and 2 was present. Of the 47 patients studied, 35 suffered from dyspnea, which disappeared in the cases in which the anemia improved. Twenty-one patients showed dependent edema, and in 10 of the 12 patients with edema who were followed, the edema disappeared with the anemia.

Because of the comparative rapidity with which the heart decreases in size once the anemia is relieved, it is generally believed that its enlargement is mainly due to dilatation. Cabot and Richardson,⁶ however, found from autopsy material that there was an increase in the weight of the heart in 18 of 19 patients dying of pernicious anemia, and Porter⁷ observed a heart weighing 630 gm. in a man dying of hookworm anemia. These findings have been confirmed by animal experimentation. In addition to dilatation and hypertrophy, the heart muscle undergoes fatty degeneration, which is usually most marked in the papillary muscles of the left ventricle, where it produces a speckled appearance under the endocardium, to which the descriptive phrases "tabby cat," "thrush breast" and "tiger-ing" have been applied. These changes in the myocardium have been produced experimentally by Campbell⁸ by subjecting animals to low oxygen pressures for long periods. Also, Opitz⁹ in 1935 described areas of myocardial necrosis in patients suffering from severe anemia, and Buchner and

*Assistant professor of pathology, Tufts College Medical School; instructor in pathology, Harvard Medical School; assistant pathologist, Mallory Institute of Pathology, Boston City Hospital.

†Associate professor of pathology, Boston University School of Medicine; instructor in pathology, Harvard Medical School; assistant pathologist, Mallory Institute of Pathology, Boston City Hospital.

had an apical systolic murmur. The lungs were clear. The hemoglobin was 52 per cent, and 2 days later dropped to 42 per cent, with a red-cell count of 2,520,000. During the hospital stay the patient passed three liquid tarry stools that showed a ++++ guaiac reaction. He was given considerable morphine and was transfused, without marked improvement of the anemia. On the 5th hospital day he developed left-sided cardiac failure with pulmonary congestion and expired within 24 hours.

Autopsy. The heart weighed 350 gm. There was moderate atherosclerosis of the coronary arteries. Microscopic sections showed moderate myocardial fibrosis. The left lung weighed 1050 gm. and the right lung 900 gm. Both lungs were very boggy and moist. Microscopic examination confirmed the gross diagnosis of marked pulmonary congestion and edema. There was a prepyloric ulcer 0.7 by 0.5 cm. in area with an eroded artery in its base. The large bowel contained much changed blood.

There were 5 other cases in this group. All the patients were over the age of sixty. They showed atherosclerosis of coronary vessels without myocardial infarction at autopsy and presented clinical and anatomic evidence of cardiac failure, which was either initiated or increased by hemorrhage. Four patients had bleeding gastric ulcers, and 1 had a bleeding duodenal ulcer.

DISCUSSION

Whenever there is severe coronary sclerosis, the myocardium suffers from the result of an actually or potentially inadequate blood supply. From the purely physiologic standpoint, it is obvious that anything resulting in a reduction of the ability of the blood to carry oxygen — reduction in the blood volume, the hemoglobin content or the number of red cells — or in a reduction in the blood pressure that is forcing the blood through a narrowed coronary tree is bound to cause a sudden increase in this inadequacy.

A hemorrhage, regardless of its origin, if severe enough will produce an anemia, a drop in blood pressure and some degree of shock. It might therefore be expected to lead to the signs of decompensation of arteries already having difficulty in carrying out their functions. So far as the heart is concerned, hemorrhage also tends to produce tachycardia, which increases oxygen need and probably per se reduces coronary circulation in relation to volume output.

A frequent but often misdiagnosed cause of hemorrhage in older patients is the erosion of a blood vessel as the result of a duodenal or gastric ulcer. The hemorrhages in these cases are apt to be severe because of the fact that the eroded artery itself is sclerotic and therefore does not easily collapse and thrombose.

It is thus easy to understand why symptoms of inadequate coronary circulation follow such hemorrhages. Why in some cases actual thrombosis of these vessels is found is perhaps harder to understand. It is well recognized that a high percentage of thromboses of the coronary arteries in older patients develop as a result of the rupture of an atheromatous focus into the lumen of a blood vessel. Sudden changes in intra-arterial blood pressure

may possibly account for the rupture of an atherocheuma through its extremely thin endothelial cover into the lumen of the blood vessel and may thus lead to thrombosis.

Severe hemorrhage therefore appears to be more hazardous for the arteriosclerotic subject than for a person with normal arteries. Therapeutically, any means that will combat both profound anemia and a serious drop in blood pressure seems to be indicated, but care must be taken because the same means used to prevent thrombosis in the coronary circulation may be equally effective so far as the vessel producing the original hemorrhage is concerned. Blood transfusion appears to be the treatment of choice, since red cells are thus replaced as well as fluid. Intravenous glucose and saline solutions should be used sparingly, since they tend to reduce the unit oxygen-carrying capacity of the blood while putting additional strain on the heart.

These cases serve to point out the potential danger of having elderly arteriosclerotic patients acting as blood donors. Two cases of probable myocardial infarction following the donation of blood have recently been called to our attention. In a similar manner, these cardiac complications are also apt to occur in elderly patients suffering from traumatic shock or hemorrhage, and preventive means should always be instituted to protect such patients from the cardiac complications described.

SUMMARY

A series of cases has been presented to emphasize that in patients with severe atherosclerosis of the coronary arteries severe hemorrhage may result in inadequate coronary circulation or coronary thrombosis.

The most frequent cause of these conditions in the present series was hemorrhage from a duodenal or gastric ulcer.

Therapy in these cases is difficult because any method used to prevent the cardiac complications due to hemorrhage may per se lead to further hemorrhage from the original source.

CLINICAL NOTE

BLOODLESS CIRCUMCISION*

JOHN M. BIRNIE, M.D.

SPRINGFIELD, MASSACHUSETTS

AN OPERATION for circumcision is often brushed aside as unworthy of the efforts of a qualified surgeon, and relegated to an intern or occasional operator without adequate instruction or supervision. The resulting hemorrhage, edema, swelling or even malformation reflects little credit on the medical profession.

The operative steps presented in this paper are designed to obviate these annoying incidents, which sometimes occur even in the practice of the more experienced surgeon. The procedures advocated are based on anatomic facts, so that it will be well to review the essential points involved.

The skin covering the pendulous portion of the penis is remarkable for its thinness, its looseness of connection with the deeper parts of the organ and its lack of underlying adipose tissue. Just in back of the corona the skin is folded inward on itself, forming a free duplication, — the prepuce or foreskin, — which covers the glans penis to a variable extent. At the constricted neck of the penis, proximal to the corona, the skin is firmly adherent to the underlying tissues, and this firm contact is continued over the corona and glans up to the mucous membrane of the urethra. (The inner layer of the prepuce is often erroneously called "mucous membrane," which it is not.) The outer and inner layers of the prepuce are composed of the same tissues, and when the foreskin is fully retracted the two layers become continuous, without any line of demarcation. Under the skin is a loose layer of connective tissue in which lie the superficial blood vessels, which in the adult may be of considerable size. When the prepuce is over the glans, it has two layers of skin and two layers of connective tissue containing blood vessels. When it is drawn back and held taut, it has one layer of skin and one layer of con-

nective tissue. Contact between the connective tissue and the skin is extremely slight.

Another important fact is not strictly anatomic. Whenever a constriction of the foreskin exists, preventing retraction or producing a phimosis or paraphimosis, the tough, almost rigid ring involves only the skin, and never the underlying connective tissue.

The usual operations of circumcision consist of some form of amputation of the prepuce; others consist of a dorsal slit. In each of these types of procedure both layers of the foreskin are incised at the same time, and consequently two layers of connective tissue, with their vessels, are cut. It is to do away with these unnecessary complications that the following technic is presented.

One first determines at what point he wishes to make his incision through the outer layer of the prepuce. The point having been chosen, the skin, only, is picked up with tooth forceps and a small slit is made in it. The blades of a pair of blunt-ended straight scissors are introduced through the slit and opened. By alternately pushing the scissors forward and opening them, the operator can easily separate the skin from the connective tissue without injuring the latter. This procedure is greatly facilitated if the foreskin is fully retracted and kept tense. If this is prevented by a constriction of the prepuce, the first undermining is done toward the constriction, which is severed from within outward without injuring the connective tissue. The flaps of preputial skin to be removed may be of any size or shape to suit the preference of the surgeon. How they are to be made and how much skin should be removed is not pertinent to this description. If the operator thinks that a dorsal slit is all that is required, it can be made in the manner previously presented.

Two points in this discussion require emphasis. In the first place, both skin layers of the prepuce should never be cut at the same time. In the second place, the skin of the prepuce should never be cut until it has been separated from the connective tissue by blunt dissection. These points may be of slight importance when one is operating on an infant or a small child, but when the patient is an adult they prove themselves worthy of careful consideration.

MEDICAL PROGRESS

DIABETES MELLITUS

ELLIOTT P. JOSLIN, M.D.*

BOSTON

IN THE following remarks on the progress in the treatment of diabetic coma and of pregnancy in diabetes I have confined myself to data from the George F. Baker Clinic for four reasons: they are more favorable and based on larger numbers of cases than are those reported elsewhere; it would be unfair to cite comparative data from other sources, because such reports often represent the results of treatment by many doctors, possibly with different ideas, on different services in a hospital and where, perhaps, the senior members of the staff are able to take a less active part in the management of the individual case; in some hospitals, facilities for laboratory work are inadequate, particularly at night and on Saturday afternoons, Sundays and holidays or the expense of such tests is so considerable that the medical staff is handicapped in securing or feels averse to ordering the same; and, finally, the classification of what diabetic coma is varies according to the author reporting the data. Regarding the last, we believe that a carbon dioxide level of 20 vol. per cent (8.8 millimols per liter) or below is the greatest common divisor. We know the term "unconsciousness" is inaccurate, because so often diabetic patients are unconscious from other causes than ketosis and because the term depends so much on the attitude and tests applied by the examining physician. A recent study¹ of causes of death of 307 diabetic patients in the period 1932 to 1942 on whom autopsies were performed, supports this statement, "The example of a cerebral hemorrhage found at autopsy as a cause of death in a case clinically diagnosed as a diabetic coma is a not infrequent occurrence."

DIABETIC COMA

The secret of success in the treatment of diabetic coma is the early and adequate administration of insulin. This is exemplified by experience based on 603 cases treated at the George F. Baker Clinic of the New England Deaconess Hospital between May 23, 1923, and December 31, 1944. Between August 21, 1940, and December 31, 1944, there were more than 9000 admissions for diabetes, with 158 deaths, and among these admissions there were 141 patients in the coma group (blood carbon dioxide 20 vol. per cent or less), with 2 fatalities. Treatment from beginning to end has been essentially the same for all cases except that the first 50 coma patients treated in the earlier period received an average of 83 units of quick-acting insulin in the

first three hours, and the last 141 an average of 206 units.[†] Of the former group 18 per cent died, and of the latter, 1.4 per cent.

During all these twenty-one years, diagnostic laboratory aid has been efficient and prompt — day and night, Saturday afternoons, Sundays and holidays. At a hint of an approaching coma admission the nursing and medical staff, young and old, are alerted, and the rule holds that, after the patient arrives, if there appears a possibility at any time until complete recovery that death might ensue within two hours, two of the older group must be in actual attendance or in close consultation.

The size of the first dose of insulin is usually determined by the clinical estimation of the degree of acidosis, bearing in mind that in a patient with a relatively recent onset of the diabetes, particularly in a child, with acidosis of short duration and with unconsciousness absent, slight or not profound, less insulin suffices than if one is dealing with diabetes or acidosis of long duration and deep unconsciousness. It is in such cases that judgment counts and physicians with large experience dare to give larger doses of insulin than those with somewhat less intimate contact with coma cases. The first dose is usually between 50 and 100 units.

Within thirty to forty-five minutes after entrance, doubt about future treatment is removed because reports of the sugar and diacetic acid in the urine and of sugar and carbon dioxide in the blood are available and, shortly after that, reports of the urinary albumin and sediment and the nonprotein nitrogen of the blood. Subsequent dosage of insulin and its frequency vary with the height of the blood sugar and the depth of the carbon dioxide. Usually the entrance dose of insulin is immediately repeated and again repeated in another hour, that is, about two hours after admission, by which time later reports of the blood sugar and carbon dioxide furnish the therapeutic indications. A few cases recover with a total of less than 100 units, especially if the referring physician has given insulin before arrival, whereas an insulin-resistant patient whose customary daily dose of insulin is 400 units may require 2500 units. As previously mentioned, the average dose administered in the last 141 cases in the first three hours — the period that counts — was 206 units.

Intravenous physiologic saline solution is begun immediately on arrival, because all coma patients

*Clinical professor of medicine, emeritus, Harvard Medical School; medical director, George F. Baker Clinic, New England Deaconess Hospital.

[†]The average of 216 units for 123 cases in the last group was reduced to 205 units by the addition of 18 cases recently treated. This series included 15 children or patients under 20 years of age several of whom had received large doses of insulin before arrival at the hospital.

are dehydrated. Seldom are less than 2 liters given in the first six hours, and only once has as much as 11 liters of fluid been administered subcutaneously, by vein, by rectum and by mouth in the course of twelve hours, as occurred in Case 15791, that of a patient who recovered under the joint care of Drs. Root and Riseman at the Beth Israel Hospital.³ This patient, profoundly unconscious, became anuric after the administration of glucose solution. She remained anuric for *nine hours* but recovered when constant intravenous salt solution was given for eleven hours. This patient is not included in our series.

Lavage of the stomach is almost invariably carried out soon after entrance, but the delicacy with which this act must be performed on a patient almost in extremis should be realized. We have never regretted emptying the stomach of a patient in diabetic coma, but despite knowledge gained through practice over many years a reluctance and a delay on various occasions to adopt this procedure have brought embarrassment later when the patient, contrary to our preconceived notions, has vomited unexpectedly large quantities of bloody gastric contents. In the long run it is safer to empty the stomach with a tube, as a rule inserted intranasally, than to have the patient regurgitate and aspirate fluid and undigested food into his lungs.

The bowels are emptied by enema, but again, one should be mindful of the weakened state of the patient.

Warm blankets and accessory heat cautiously applied are utilized to bring the temperature of the body up to normal from its customary subnormal level. Fever spells a complication.

The determination of the blood carbon dioxide content is of great value in the estimation of the patient's condition. Some excellent writers depend in large measure for diagnosis and treatment on the presence, degree or absence of consciousness. Unconsciousness is a variable feature and rests on a clinical impression. Its existence varies to a considerable extent with the response of the patient to stimuli of sound or pain, and such stimuli vary from doctor to doctor. Moreover, the patient may be deaf, or the unconsciousness due to a cerebral hemorrhage, with an accompanying slight acidosis or even actual diabetic coma, and it is not rare in infections with children. The level of the carbon dioxide is a concrete fact and not open to clinical error. More and more patients are sent into the hospital for diabetic coma with conditions that have no relation to it; in such cases, knowledge concerning the carbon dioxide level is extremely helpful. Whether or not one believes in the value of the carbon dioxide determination as a therapeutic indication, it remains in our minds as the best diagnostic criterion, the greatest common divisor of all the symptoms and signs of diabetic coma and the best basis for the comparison of different methods of treatment.

Alkalies have not been given to our patients since 1917, and that type of treatment will not be discussed. Indeed, in few clinics are they generally advocated today, particularly in appreciable amounts.

Two of our 141 patients in coma died. The first (Case 22682) was a nineteen-year-old girl, admitted on April 10, 1943, diabetes having first been discovered in the same month. Acidotic symptoms began thirty hours previously, in the course of a sinus infection. When she was transferred to us from another hospital because of anuria, she was moribund, her pulse was 140, and the temperature 101.4°F., and she had received 100 units of insulin. With the administration of more insulin and 5000 cc. of saline solution the blood sugar fell from 534 mg. to 165 mg. per 100 cc. and the carbon dioxide rose from 12 to 21 vol. per cent. She was seen by various specialists, but operation was deemed inadvisable, and she died six and a half hours after admission. Autopsy showed purulent infection of both the sphenoid and ethmoid sinuses, early bronchopneumonia and atherosclerosis of aorta. Death was caused by sepsis due to a hemolytic *Staphylococcus aureus*. The other patient (Case 24095) entered with a coronary thrombosis of 'twelve hours' duration and lived an hour and a half; the autopsy showed occlusion of both coronary arteries.

A third patient (Case 23935) is not included in our series. He was 19 years old and had had diabetes for two years. He entered following coma but without the presence of acetone or diacetic acid in the urine and with a blood carbon dioxide of 23 vol. per cent. He was unconscious and had been given elsewhere 400 gm. of glucose in the first twelve hours of treatment. He was not suffering from severe acidosis, but from glucose administration. The blood sugar was 680 mg. per 100 cc. He received 320 units of insulin, with the result that the blood sugar value at the end of six hours had fallen to 222 mg. and that the carbon dioxide level at the end of three hours had risen to 40 vol. per cent. He lived nine hours. Autopsy showed slight atherosclerosis of the aorta and early pulmonary congestion.

Glucose has not been used in our clinic in the early stages of the treatment of diabetic coma since 1917. It is administered as soon as the amount of sugar in the blood approaches a nearly normal level and the urine is nearly or quite sugar free. Our design is to provide during the first twenty-four hours of treatment that the carbohydrate intake by mouth or vein shall be not less than 100 gm.

Glucose is advocated by some clinicians on the basis that it will be oxidized and that its oxidation will favor the oxidation of beta-oxybutyric acid and its derivatives. The experiments or remarks of Soskin and Mirsky are cited to support this contention. Our ideas can perhaps best be presented in the form of questions and answers.

Is the body of the patient in diabetic coma lacking in carbohydrate? It is not. Table 1 shows a comparison by Dr. H. F. Root⁴ of the carbohydrate in a normal man, weighing 70 kg. with that of a patient of similar weight in diabetic coma with a blood sugar level of 700 mg. per 100 cc. Soskin⁵ used the same figures for normal persons, but he did not include the skin. In coma he considered that the blood

not over 20 calories per kilogram, or approximately 1400 calories. As soon as serious acidosis is relieved, the carbohydrate stores can again be replenished.

What has Mirsky said about glucose in diabetic coma? He⁹ writes as follows:

It must be emphasized that a distinction should be made between hyperglycemia due to a high carbohydrate intake and that due to endogenous sources. In the former, the high blood sugar merely reflects the character of the diet and indicates that an increased amount of substrate is available for deposition in the liver; in the latter, the hyperglycemia represents a disturbance of regulation of such a degree that formation of dextrose and breakdown of glycogen are accelerated. Needless to say, excessive amounts of carbohydrate, such as we used, are contraindicated as a therapeutic procedure because of the polyuria and resultant loss of weight on the one hand and the possible danger of pancreatic exhaustion on the other.

TABLE 1. Carbohydrate Stores in a Normal Person and Patient with Diabetic Coma.

SOURCE	NORMAL		DIABETIC COMA	
	CONTENT	TOTAL	CONTENT	TOTAL
	%	gm.	%	gm.
Muscle, 30 kg (glycogen) . . .	0.6	180	0.3	90
Liver, 1800 gm (glycogen)	6.0	108	1.0	18
Skin (glucose)	0.08	4	0.56	28
Extracellular fluid, 21 kg. (glucose) .	0.08	17	0.70	146
Totals		309		282

sugar was 0.35 mg. per 100 cc. and that the reduction of the glycogen stores might be greater than that shown in the table.

According to the respiratory quotients of 0.68 and 0.69 observed and reported by Root and Carpenter,⁶ no significant quantity of carbohydrate is oxidized during diabetic coma. The respiratory quotient was not raised by glucose alone, but was raised when sufficient insulin was given.

Is glucose injected into the vein burned any better than glucose already present in the body? No. Glucose given by vein is no better oxidized than the glucose already present in excess. Indeed, when Root and Carpenter⁶ compared in normal students the effects of 50 gm. glucose by vein and by mouth, the increases in carbohydrate combustion during the two and a quarter hours after intravenous injection were a little less than those when the glucose was given by mouth, the respective averages for four subjects being 9.0 gm. and 10.6 gm.

How much carbohydrate does a man weighing 70 kg. burn an hour when at rest and when at moderate work without food? Such a man burns 5 to 6 gm. at rest and may burn as much as 30 gm. in an hour at moderate work. In hyperthyroidism, the former figure only rises to 6.4 gm.^{7, 8}

How much carbohydrate must be burned hourly to avoid acidosis? This is variable. The diabetic patient who assimilates 100 gm. of carbohydrate per 24 hours shows no significant acidosis.

What has recently come from Soskin's pen on this subject? Soskin's⁵ recent article emphasizes the primary place of insulin in the treatment of diabetic coma, but he states that in the first twenty-four hours such a patient needs 500 gm. of carbohydrate to return the glycogen stores to normal and to provide 50 per cent of the 2100 calories required in that period. Actually, it is known that the patient in diabetic coma should have his total metabolic rate reduced by rest in bed and by a diet consisting of

Why is the administration of glucose harmful in diabetic coma? There are several reasons. In the first place, it obscures an estimation of the progress of the case toward recovery, because the blood sugar level is no longer a measure of adequate insulin dosage. Secondly, it may injure the liver.¹⁰ Thirdly, it may provoke anuria, or if not burned, may deplete the body of fluid. Finally, in 17 cases of diabetic coma seen by Dr. H. F. Root¹¹ in consultation, submitted to him for review or published in extenso in the literature in which the patients received large amounts of glucose early in the course of the attack and before adequate insulin had been given, the mortality was 100 per cent. Of course, 25 or even 50 gm. of glucose will not kill the patient who first receives insulin in amounts sufficient to utilize the excessive glucose in the blood and extracellular fluid of the body, as indicated by a decline of the blood sugar to a normal level.

Dr. John P. Peters, of New Haven, in a personal communication says that his initial priming dose of glucose is approximately 25 gm. along with insulin and thereafter, including the first dose, is kept up at the rate of about 10 gm. per hour until the blood sugar begins to decrease, when the carbohydrate is increased and the insulin is diminished according to the condition of the patient.

To this discussion I am allowed to add a pertinent comment by Dr. Charles H. Best, of Toronto:

Although there are a number of conditions characterized by a low level of glycogen in the liver in which there is deficient oxidation of carbohydrate in the body, there are, on the other hand, conditions that deplete liver glycogen, such as severe muscular exercise and the administration of thyroid hormone, which are certainly not associated with impairment of carbohydrate oxidation. In other words, it would not appear to be a low level of liver glycogen per se that interferes with the oxidation of carbohydrate.

ALLOXAN

Alloxan still holds the center of experimental investigation in diabetes mellitus. The prominence given to it in the progress report of a year ago¹² is justified by the articles about it that have appeared

In other words, it would not appear to be a low level of liver glycogen per se that interferes with the oxidation of carbohydrate.

ALLOXAN

Alloxan still holds the center of experimental investigation in diabetes mellitus. The prominence given to it in the progress report of a year ago¹² is justified by the articles about it that have appeared

in Scotland, Argentina, Chile, England, India, Mexico and Canada as well as in the United States. In the following section an attempt is made to present recent work that has extended knowledge concerning the effects of this diabetes-provoking chemical, which has such a highly selective action and affinity for the beta cells of the islands of Langerhans — all told, they comprise only about 0.007 per cent of the weight of the entire body, the equivalent in weight of a lump of sugar — that it destroys them within a few hours, leaving the remainder of the body intact.

In recapitulation it may be said that alloxan is the ureide of mesoxalic acid. When 200 mg. per kilogram of body weight are injected intravenously into a rabbit, hyperglycemia occurs for one or two hours, followed by extreme hypoglycemia, which, if untreated with glucose or food, usually results in the death of the animal within twenty-four hours. If the animal is prevented from dying in hypoglycemia, diabetes results. Autopsy reveals extensive necrosis of the islands of Langerhans, with destruction of the beta cells but sometimes without notable injury to the alpha cells. The acinar tissue and other parts of the body escape injury unless the dose of alloxan has been excessive. Such animals can be maintained with insulin for over a year, exhibiting severe diabetes with lipemia and acidosis. Similar results have also been obtained with rats and dogs.

Hughes, Ware and Young¹³ have produced a state of hyperglycemia followed by hypoglycemia, similar to that which is observed after an injection of alloxan, by the injection of adrenalin and an amount of protamine zinc insulin equivalent to that estimated to be present in the pancreas of a normal rabbit, namely, 10 units per kilogram of body weight. This suggests that the initial hyperglycemia may be due to adrenalin excretion and that the hypoglycemia is not caused by an over-activity of the beta cells, as was once surmised, but rather by the liberation of preformed insulin. This explanation received additional support by the fact that Hard and Carr¹⁴ and others¹⁵ noted that the islands of Langerhans begin to show pathologic change within five minutes after the injection of alloxan. More conclusive evidence was presented by an ingenious experiment of Goldner and Gomori,¹⁶⁻¹⁸ who removed the adrenal glands or destroyed the adrenal medullas of rabbits by intramedullary injections of formalin. A diabetogenic dose of alloxan was then given, and in no instance did initial hyperglycemia develop. Severe hypoglycemia occurred, presumably enhanced by the lack of adrenal counter-regulation factor. They conclude that adrenal stimulation of glycogenolysis is involved in the production of the initial transitory alloxan hyperglycemia. Beta-cell degeneration occurs within the first hour and precedes the hypoglycemia, which usually develops only after four

or five hours. Whenever hypoglycemia develops, diabetes follows if the animal survives. On the other hand, Banerjee,¹⁹ although losing three rhesus monkeys with hypoglycemia following injections of 300 mg. alloxan per kilogram, observed that three others developed diabetes, although their blood sugar levels remained persistently high.

Degeneration of the beta cells with the decrease in insulin production has been demonstrated by insulin assay of the pancreases of Goldner and Gomori's dogs with alloxan diabetes of eighteen, thirty and sixty days' duration. The pancreases of these dogs contained only about one fourth of the 2 to 3 units of insulin per gram contained in those of normal dogs.

Ridout, Ham and Wrenshall²⁰ have shown in both cats and dogs that the insulin content of the pancreas did not fall appreciably until most islet cells were found by histologic examination to be dead. In other experiments they found that alloxan did not exert a hypoglycemic effect in depancreatized dogs or in dogs previously made diabetic with alloxan. (See also Haist²¹ for a comprehensive review including nearly two hundred citations covering the whole question of the insulin content of the pancreas and the factors affecting it.)

Abolition of the initial hyperglycemia subsequent to an injection of alloxan does not prevent the development of alloxan diabetes.¹⁶⁻¹⁸ This is in sharp contrast to the diabetes produced by injections of anterior pituitary extract or by partial pancreatectomy, in both of which the diabetes is prevented if hyperglycemia is counteracted by insulin, phloridzin or starvation.

Bailey and Bailey²² produced diabetes in rabbits with 200 mg. of alloxan per kilogram body weight in a single dose and also with repeated injections of 40 mg. per kilogram in a succession of seven to thirteen doses over a period of one to three weeks. In the latter animals histologic examination revealed a variety of changes in the islets of Langerhans. Some cells revealed hydropic degeneration, which in many instances is known to be reversible, whereas other cells showed irreversible changes and still others were normal. They report the occurrence of diabetic cataracts in both rabbits and rats and suggest that the administration subcutaneously of 200 mg. of alloxan per kilogram is a feasible method of producing diabetes in rats. Carrasco-Formiguera²³ not only observed a marked variation in the severity of alloxan diabetes in dogs but also reports a recovery from the diabetes. One dog, after exhibiting mild glycosuria and hyperglycemia for a few days as a result of an injection of alloxan, at which time it showed a mildly diabetic dextrose-tolerance test, gave a normal sugar-tolerance test forty-two days after the alloxan injection. This animal was therefore cured after a mild but unmistakable diabetes.

Kennedy and Lukens²⁴ point out the differences in the susceptibility of individual animals and of

different species to alloxan. Like Hard and Carr and Goldner and Gomori, they found that an animal refractory to alloxan usually does not respond to successive doses. They noted incidentally that animals—dogs, cats and rabbits—under barbiturate anesthesia, when injected with effective doses of alloxan, died; but others²⁵ have found it possible to produce alloxan diabetes in such rabbits by the injection of a diabetogenic dose of alloxan. Kennedy and Lukens noted no increase in mortality with light ether anesthesia. These authors also emphasize that alloxan is effective in rabbits when given intravenously but ineffective when administered subcutaneously or intraperitoneally, which suggests that it is rapidly altered when in contact with the tissues. In the rat, however, it is effective when given subcutaneously or intraperitoneally.

The rabbits of Kennedy and Lukens excreted 15 to 60 per cent of the available glucose of the diet, and the glycosuria was reduced by fasting. In 4 rabbits there was no evidence of improvement in the diabetes when the diabetes was controlled by insulin. Contrary to the experiments of Bailey and Bailey,²² they noted no cataracts in rabbits made diabetic by alloxan after a duration of six weeks or longer.

They also observed that alloxan does not inactivate insulin *in vitro*. They state that hydropic degeneration was observed post mortem in the islet tissues of 2 rabbits with diabetes of one to two months' duration. This is ascribed by them to the effect of hyperglycemia on the beta cells that escaped destruction by alloxan.

In an article on the morphologic and physiologic changes of alloxan diabetes in the rabbit, Bailey, Bailey and Hagan¹⁵ emphasize the specificity of action of alloxan, describe the pancreatic-islet changes at intervals after its injection, citing changes even after five minutes, and state that these changes are degenerative from the beginning. Only a certain percentage of alpha cells remain intact, as compared with the lesion in experimental pituitary diabetes, in which there is no destruction of the alpha cells. They observed that the lesions in the kidney of the alloxan diabetic rat were severer than those in the rabbit, all changes in rabbits outside the pancreatic islets being minimal. The lack of cellular response to the necrosis of the islands is remarkable. In almost all other forms of necrosis, neutrophils may be seen at one stage or another. This unusual response to alloxan, therefore, offers a biologic problem of considerable interest. The lesions that were produced by small doses of alloxan resembled all the well-known lesions of the islands in human diabetes. In addition the histologic lesions in the different phases of the blood sugar curve represent one continuous process.

Further discussion of the histologic changes in alloxan diabetes has appeared from the Pathological Department of the University and Western In-

firmary, Glasgow.²⁶ These authors, too, noted that definite histologic changes can be recognized in the islands in about an hour and may be pronounced in three hours, when some beta cells appear to be necrosed. They also remark:

With doses of 50 mg. per kilogram the beta cells sometimes show degranulation, but little necrosis. At twenty-four hours the appearances are consistent with abnormal increase of function. After these smaller doses islet changes may be only slight and focal in distribution. Alpha cells are less prone to the necrobiotic changes than beta cells and, from early states, may be enlarged with apparent increase of granules when the beta cells are necrosed or exhausted: this observation suggests some difference in function of the two types of cell. A temporary hyperglycemia almost always occurs in the first two hours where there is any damage to the islets.

Hooded rats were supposed to be resistant to alloxan, but Duff and Starr²⁷ have found that alloxan injected subcutaneously into these animals in doses of 175 to 350 mg. per kilogram of body weight regularly produced rapid selective necrosis of the islands of Langerhans and characteristic fluctuations of the blood sugar level. Histologic alterations in the islets of Langerhans conformed to those described with white rats, but in addition, a great increase was observed in the activity of mitotic division in the acinar cells during the first twenty-four hours after the injection of alloxan. Hypoglycemic convulsions were not observed. The urine collected during the first six hours was pink, resembling the color that results when alloxan is allowed to evaporate in air. With large doses of alloxan, and sometimes with small ones, the blood sugar rose at times to 800 to 1450 mg. per 100 cc., with death in a state suggestive of diabetic coma, accompanied by massive glycosuria and acetonuria. With smaller doses the animals usually survived for weeks or months without treatment, with blood sugar levels of 300 to 500 mg. per 100 cc. They, too, observed that at one hour after injection histologic changes in the islands were apparent. Most of the destruction occurred in the beta cells, but there were also some necrotic alpha cells. In addition there was a notable increase in the mitotic activity of the acinar cells. With the exception of slight degenerative changes in the convoluted tubules of the kidney and slight fatty metamorphosis of the liver, there were no significant alterations in other organs. Sections of the livers from diabetic animals were lacking in glycogen. Glycogen in the heart muscle was not more than normal, but glycogen in the renal tubular epithelium, especially that of the loops of Henle, was demonstrated in several animals.

Lackey, Bunde, Gill and Harris²⁸ recall that the glycogen in the heart of a dog or a cat is increased by pancreatectomy. Since both exocrine and endocrine secretions are eliminated by pancreatectomy, they investigated the glycogen problem in rats previously made diabetic with alloxan. The alloxan-treated animals, as compared with the controls, showed a statistically significant increase in glycogen

content of the heart muscle and a statistically significant decrease in that of the liver and skeletal muscle. Rappaport²⁹ claims that brain slices of alloxanized rats, like those of normal rats, consume more oxygen when glucose is present in the medium than when it is not. The evidence indicates that in the rats suffering from this form of diabetes there is no impairment in the ability of the brain to oxidize sugar.

Koref, Vargos, Rodriguez and Telchi,³⁰ working in Chile, have produced necrosis of the islands of Langerhans, where others have failed, with the use of alloxantin, which can be regarded chemically as an oxidation product of uric acid or a reduction product of alloxan. This finding has been confirmed by Bailey and Bailey.³¹ Alloxan dissolves fairly well in cold water, whereas alloxantin has a low solubility in cold but is fairly soluble in hot water. Another distinguishing mark between the two is that alloxan gives a white precipitate with barium hydrate, and alloxantin a violet one. They therefore used solutions of 1.0 and 2.5 per cent alloxantin at about 50°C. in doses of 70 to 230 mg. per kilogram of body weight. The smaller concentration was the more toxic. Many of the rabbits died before diabetes developed, but others had typical diabetes. Histologic examination showed, as with alloxan, lesions in the islands of Langerhans—cellular degeneration and necrosis, marked diminution of the beta cells and, in cases of long duration, a diminishing amount of islet tissue. They state:

It would appear that alloxantin may produce experimental diabetes, but there are apparently certain differences from the effects of alloxan. First of all there is the paradoxical effect that the lower concentrations, even administered in small doses, are more toxic than the larger doses in higher concentration. This may be explained by the supposition that the alloxantin, like alloxan, is mainly a capillary poison. If such a compound is administered in higher dilution, its diffusibility will be increased, especially in cases of relatively insoluble substances. Consequently it could paralyze more rapidly the capillary system. Higher concentrations with tendency to crystallize may act more slowly, developing rather the symptoms of subacute intoxication. The second fact is that none of the animals treated in our experiments with alloxantin developed hypoglycemic shock, although we could demonstrate that the blood sugar figures reached a very low level.

Thorogood³² injected 50 rats subcutaneously with 200 mg. of alloxan per kilogram of body weight and found that 10 developed diabetes, 10 were not affected and 30 died. Others²¹ observed that 12 of 15 rats developed diabetes with this dosage subcutaneously.

Banerjee¹⁹ reports the production of alloxan diabetes in 3 of 6 monkeys given 300 mg. of alloxan per kilogram of body weight. The remaining 3 died in hypoglycemia.

Recently, Leech and Bailey³³ reported a test for the detection of alloxan in the blood. Using this test they demonstrated that alloxan reaches its highest level at the end of the injection, following which it rapidly decreases, with a complete dis-

appearance in five minutes. This coincides with the finding of Goldner,¹⁶⁻¹⁸ who reports that, if a part of the pancreas is temporarily deprived of its blood supply for five minutes after the injection of alloxan and the temporary blood ligatures are then released, that part of the pancreas escapes injury, showing that the damage occurs within the first five minutes. Leech and Bailey further found the reduced glutathione in the blood was markedly decreased, in some cases to zero, immediately after the injection of alloxan, which suggests an interaction of these two substances. Another sulfhydryl compound, —thionine, — in the 2 cases tried, seemed to follow a similar change.

Since the injection of both anterior pituitary extract and alloxan may produce diabetes in animals, it seemed important to find whether alloxan acted through the pituitary gland. Bailey³⁴ proved that alloxan did not exert its diabetogenic effect in this way, since hypophysectomized rats given alloxan developed diabetes, with characteristic necrosis of the islets of Langerhans.

PREGNANCY

Recent publications indicate that the obstetrician and the internist now agree that, whereas the maternal mortality in pregnant diabetic women has been low, the fetal mortality has been high, from 30 to 60 per cent, depending on the duration of the pregnancy.³⁵⁻³⁷ Between January, 1936, and January, 1945, a study of 210 consecutive pregnancies in diabetic women was made at the George F. Baker Clinic.³⁸ In this series 209 mothers and 176 babies survived. An analysis of these cases indicates that a high fetal mortality is preventable.

Maternal, obstetric, chemical and fetal abnormalities characterize pregnancy in the diabetic patient. Thus, diffuse vascular disease and hypovarianism are frequent complications, and more often than not the pregnancies occur in physically and gynecologically aged patients. In the uncorrected course of diabetic obstetrics, early spontaneous interruption of the pregnancy occurs in 25 per cent of the cases, toxemia in 33 per cent, and breech presentations in 33 per cent. Uterine inertia is of common occurrence, and lactation rare. Chemical abnormalities include a low renal threshold for glucose, which favors the development of acidosis and hypoglycemia, water retention in the maternal tissues, amniotic sac and fetus and an imbalance of the sex hormones of pregnancy comprising a rise of chorionic gonadotropin and a fall of estrin and of progesterone, the last having been found in 70 per cent of our cases. Of the fetal abnormalities, overweight occurs in 80 per cent of the uncorrected cases, obesity, edema and splanchnomegaly being contributory factors. Excessive hematopoiesis of the liver and spleen and islet hyperplasia have been observed in nearly all fatal cases. Atelectasis is the

most frequent and important neonatal complication.

Although all these abnormal factors contribute to fetal mortality, the imbalance of the sex hormones of pregnancy appears to be the most harmful factor. In 58 cases in which the sex-hormone balance was normal there were no premature deliveries, 2 per cent of the patients developed toxemia, and 97 per cent of the infants survived. Among the 41 cases with an imbalance of sex hormones, 40 per cent of the patients delivered prematurely, about 50 per cent developed pre-eclamptic toxemia, and only 54 per cent of the infants survived. Estrin and progesterone were administered in 110 cases with the hormonal imbalance. Fifteen per cent of patients delivered prematurely. The incidence of toxemia in patients treated throughout pregnancy dropped to 5 per cent, and fetal survival rose to 89 per cent.

The therapy recommended is as follows: 1 or 2 gr. of Armour's thyroid daily, from the beginning of pregnancy; proluton in ascending doses, from the diagnosis of pregnancy to the sixteenth week, 5 mg. three times a week, from the sixteenth to the twentieth week, 5 mg. daily, from the twentieth to the twenty-fifth week, 10 mg. daily, from the twenty-fifth to the twenty-eighth week, 15 mg. daily, from the twenty-eighth to the thirty-second week, 20 mg. daily, and from the thirty-second to the thirty-seventh week 30 to 40 mg. daily; and stilbestrol likewise in ascending doses, from the twentieth to the twenty-fourth week, 10 mg. daily, from the twenty-fifth to the twenty-eighth week, 15 mg. daily, from the twenty-ninth to the thirty-second week, 20 mg. daily, and from the thirty-second to the thirty-seventh week, 30 to 40 mg. daily. The diet should include liberal quantities of carbohydrate and protein; salt should be omitted after the sixth month. Insulin is usually necessary before lunch and supper, in addition to the breakfast dose.

The time for delivery is the thirty-seventh week, and we believe that the method of choice is cesarean section, without medication and under spinal anesthesia.

The welfare of the infant is aided by oxygen incubation, mechanical stimulation, dehydration and drainage.

It does not seem illogical to believe that the vascular disease and hormonal imbalance of the young diabetic woman predispose her to the vascular disease and hormonal imbalance of pregnancy — a prematurely aging patient — and a prematurely aging placenta.

STATISTICS

A preliminary and round figure for diabetic deaths in the United States for 1943 is 37,000, a rate of 27.6 per 100,000.³⁹ New York leads with 43.6, Rhode Island follows with 43.0, and Massachusetts is third with a rate of 39.4. The percentage increase

in the total United States for the three years 1930–1932, as compared with the three years 1940–1942, was 27 per cent. By states, Oklahoma and Arizona led with increases of 48 and 47 per cent, respectively; the higher rates, however, were only 15.2 and 11.9 per 100,000. The increases in New York, Rhode Island and Massachusetts were respectively 40, 27 and 38 per cent.

Rates for the industrial insured cases of the Metropolitan Life Insurance Company for the period 1939–1944 have varied from 27.4 per 100,000 in 1941 to 29.8 in 1940; the rate for 1944 was 27.6.

DIABETES ABSTRACTS

Mention should be made of the great contribution to the diffusion of knowledge concerning diabetes that has been afforded by the joint publication of *Diabetes Abstracts* by the American Diabetes Association and the Eli Lilly Company. Four numbers appear yearly. They contain an exceptionally careful summary of all current papers on various aspects of the disease. The time thus saved to the physician is almost incalculable.

CASE 31081

PRESENTATION OF CASE

A fifty-four-year-old dishwasher was admitted to the hospital complaining of dyspnea, chest pain and rusty sputum.

The patient was well until about one month prior to admission, when he developed a persistent slightly productive cough following an upper respiratory infection. Five days before entry he developed generalized aches and pains, with malaise and a shaking chill. On the following day he experienced a second chill. He noted slight sharp pain in the right chest on inspiration and increasing dyspnea. Three days before entry he began to cough up rusty sputum.

The patient had had urgency and nocturia (two to three times) for several years, associated with difficulty in starting and a diminution in the force of the stream. He had had some dyspnea on climbing one flight of stairs, but there was no history of orthopnea, ankle edema or pain in the legs. He drank six to eight glasses of beer daily and whisky occasionally.

Physical examination revealed a well-developed and well-nourished, slightly cyanotic and dyspneic man appearing acutely ill. The skin was hot and moist. The pupils were somewhat irregular, and the fundi revealed slight tortuosity of the vessels, with arteriovenous nicking. Over the right lower lung field, more marked posteriorly, there were dullness, increased tactile and vocal fremitus, and diminished breath sounds. A Grocco's triangle was present on the left. The heart sounds were poorly heard. A marked aortic systolic murmur, accompanied by a thrill, was heard over the precordium, with maximum intensity about 5 cm. to the right

of the sternum in the second intercostal space; it was transmitted to the right axilla and through to the back on the right. The abdomen was distended and tympanitic. The knee jerks were diminished, and the ankle jerks absent.

The temperature was 103°F., the pulse 110, and the respirations 24. The blood pressure was 100 systolic, 50 diastolic, in the right arm, 115 systolic, 70 diastolic, in the left arm, and 150 systolic, 70 diastolic, in both legs.

Examination of the blood revealed a red-cell count of 3,370,000, with 12.3 gm. of hemoglobin, and a white-cell count of 10,000, with 94 per cent neutrophils, of which 74 per cent were band forms. There were marked toxic granulations in the neutrophils. The urine had a specific gravity of 1.015 to 1.020, with a ++ test for albumin on admission but none thereafter; there was an occasional white cell and coarsely granular cast in the sediment. The stools were negative. The serum nonprotein nitrogen was normal, and the protein was 5.4 gm. per 100 cc., with an albumin-globulin ratio of 1.9. The prothrombin time was 24 seconds (normal, 18 to 20 seconds), and a cephalin flocculation test was negative. A bromsulfalein test showed 15 per cent dye retention. A sputum culture on admission revealed an abundant growth of Type 5 pneumococci, and a culture five days later showed a few beta-hemolytic and many alpha-hemolytic streptococci. Five blood cultures were negative. An electrocardiogram showed slight left-axis deviation, biphasic T₁ and T₂, flat T₃ and sagging ST segments in Leads 1, 2, CF, and CF₃, findings consistent with left ventricular strain and hypertrophy.

A roentgenogram of the chest revealed density in the right lower lung field. There appeared to be some widening of the right side of the mediastinum. The left lung field was clear. A repeat film three days later showed considerable density remaining in the right lower lung field; this was definitely within the lung. There was no other change.

Soon after admission the temperature spiked to 106°F., after which it ranged between 101 and 103, with occasional spikes to 104. Respirations averaged about 30. A tap of the right chest yielded slightly viscid, cloudy fluid containing fibrin; there were 50 cells per high-power field, 98 per cent of them being polymorphonuclears. Sulfadiazine therapy was instituted, following which the white-cell count fell to 3800. On the fifth hospital day, sulfadiazine was stopped and penicillin substituted. The white-

*On leave of absence.

cell count gradually rose to 12,000. A second thoracentesis, on the seventh hospital day, was productive of 650 cc. of viscid cloudy fluid having a specific gravity of 1.020 and a white-cell count of 4300, with 65 per cent polymorphonuclears. A culture of the fluid revealed *Staphylococcus aureus*. On the following day the patient complained of sharp pain on inspiration over the right lower chest, but no friction rub could be heard in this area. Fluoroscopy on the ninth hospital day revealed a wide mediastinum, an active expansile pulsation in the upper chest to the right of the midline, and what

sternum in the upright than in the supine position.

On the fourteenth hospital day a therapeutic test with three 200-r doses of x-ray was begun. The patient showed no subjective change, and the temperature continued to range from 101 to 102°F. Penicillin was stopped on the twelfth hospital day, and 0.1 gm. of digitalis was administered three times daily. A roentgenogram of the chest on the eighteenth hospital day showed the density over the right lower lung field to have largely disappeared. Only a small amount of fluid remained in the right pleural cavity. The heart and mediastinum were markedly dis-

FIGURE 1.

appeared to be collapse of the right lung at the base, with only a minimal amount of fluid. Examination of the chest showed decreased resonance at the right base, with diminished breath sounds and a few rales, especially posteriorly. There was dullness over the hilar region in the right posterior chest. Examination of the heart revealed the point of maximum intensity to be 10.5 cm. to the left of the midsternal line and 1.5 cm. beyond the left midclavicular line in the fifth intercostal space. The loud aortic murmur, as well as the thrill, was transmitted over the whole chest and into the neck, abdomen and back. It was loudest about a centimeter nearer the

placed to the right, and in the lateral view there was a suggestion of collapse of the greater part of the right lower lobe. The heart was enlarged, particularly in the region of the right ventricle. The aorta was tortuous and calcified, but there was no demonstrable evidence of aneurysm (Fig. 1). On the twenty-fourth hospital day, the temperature rose to 103.4°F. and the patient complained of intense pain over the right lower chest on inspiration. The breath sounds over the right middle lobe were absent, and the heart sounds were muffled. Fluoroscopy and roentgenograms of the chest revealed that the pulsations of the heart and aorta were much smaller

-than at the time of the previous examination. A large area of calcification was visible in the valvular area of the aorta, but there did not seem to be any appreciable aortic widening.

On the twenty-sixth hospital day the patient suddenly complained of intense and persistent chest pain; he died two hours later.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: "A fifty-four-year-old dishwasher was admitted to the hospital complaining of dyspnea, chest pain and rusty sputum." It sounds like lobar pneumonia, and the story of the illness immediately preceding entry also sounds like pneumonia.

The urgency, nocturia and so forth suggest that he had prostatic difficulty, but nothing more is said about it. In the story later on we find that he had a normal serum nonprotein nitrogen.

"He drank six to eight glasses of beer daily and whisky occasionally." I shall take that statement at face value, and I must say that it is not a terrific alcoholic history.

It is stated that there were diminished breath sounds with increased tactile and vocal fremitus. I doubt it; at least it does not sound reasonable.

"Grocco's triangle was present on the left." In other words, there was contralateral dullness.

The diminished knee jerks probably were of no consequence. The problem of obtaining ankle jerks in an extremely sick man makes that observation doubtful.

We still have evidence consistent with consolidation of the lungs, which is also consistent with pneumonia, and nothing so far to suggest that this patient did not have pneumonia. There is, however, the possibility of a heart lesion. The findings in the heart suggest calcareous aortic stenosis. The question is whether or not to take seriously the difference in blood-pressure readings in the two arms. To my mind the difference is not great enough, at least on the single observation, to put much stress on the finding.

The white-cell picture, with 94 per cent neutrophils, is certainly consistent with a fairly severe, acute pyogenic infection. Although we are not told what the other 6 per cent were, I assume that they were lymphocytes and that there were no eosinophils and no monocytes. The marked toxic granulations of the neutrophils can be overemphasized, but taken with the differential picture it is strong evidence in favor of an acute pyogenic infection. It is equally strong evidence against infection such as subacute bacterial endocarditis or septicemia without an acute exudative process, such as an abscess or something of that sort.

DR. BENJAMIN CASTLEMAN: The remaining 6 per cent in the differential count was composed of 2 per cent large lymphocytes, 2 per cent small lymphocytes and 2 per cent monocytes.

DR. RICHARDSON: Although there are too many monocytes, the white-cell picture is consistent with and quite suggestive of pneumonia.

I might as well get the anemia out of the way. The red-cell count of 3,300,000 indicates a fairly definite anemia. I should like to point out that red-cell counts are not so accurate as they are thought to be. It is known that, when they are done by well-trained technicians on the same patient and repeated, they can vary as much as half a million or more in either direction. Of course, that does not mean that the error is always going to be that much. One cannot take a single observation too seriously; however, one must assume that this anemia meant something. That brings us down to the hemoglobin. In the general wards of this hospital it is presumably done by the Sahli method, and *one should not be too impressed by the figure 12.3 gm.* The Sahli method is full of snares and delusions—I fear that I am going to be hypercritical, even iconoclastic, about this. The Sahli test may vary as much as 25 per cent if one uses a yellow light, a filter light or daylight. Furthermore, the standards may fade, and although it is desirable frequently to calibrate them, they almost never are calibrated. With a faded standard the reading is obviously too high. This particular blood works out as a macrocytic anemia with a color index of 1.3.

DR. CASTLEMAN: Five days after the first blood examination the red-cell count was 3,800,000; the differential white-cell count was 77 per cent neutrophils, of which 40 per cent were band forms with toxic granules, 12 per cent large lymphocytes, 8 per cent small lymphocytes and 3 per cent monocytes. A red-cell count done two weeks later was 3,600,000, with a hemoglobin of 10.5 gm.

DR. RICHARDSON: That would be a normochromic anemia.

The anemia should be explained, and I find it one of the most difficult things in this record to do. Anemia of course can occur with sepsis, but it usually follows chronic sepsis. One would expect it to be a little slower in developing. It is possible, however, that it was due to chronic sepsis. Anemia due to malignant tumors, provided the tumor is not in the gastrointestinal tract and associated with blood loss, or possibly a nutritional element, shows a considerable degree of regeneration. If one saw a smear with an anemia of that degree and then found numerous nucleated red cells or polychromatophilia with stippling or other evidence of regeneration, it would be suggestive of a malignant tumor. I do not believe that malignant tumor of itself produces anemia of this type. I do not know what the red cells looked like, as a matter of fact, and therefore one has to consider that this anemia may have been due to lack of liver principle or to some nutritional disturbance. The anemia of uremia may produce toxic granules, but we are told later on that the

patient had no uremia. One more point about the hemoglobin: I find that the most satisfactory method of hemoglobin determination, except for photoelectric measurement, is that given by the Tallqvist scale, using one of the old books. I expect that I shall hear a lot more about this statement later on.

DR. J. H. MEANS: I may say at this point that I think you are quite right. One has to add, however, that the person taking it should back up against the window and read it in daylight.

DR. RICHARDSON: It has to be read right away. The paper must be folded over double and the person should have his back to daylight. Using the old scales I can get a fair correlation with the photoelectric determination. It is not a falsely accurate test the way some of the others are.

"An electrocardiogram showed . . . findings consistent with left ventricular strain and hypertrophy." I shall accept that statement and make no further comment.

"Sulfadiazine therapy was instituted, following which the white-cell count fell to 3800." I still think that this story is consistent with an acute infection of the lung that had not resolved.

The fluid in the right lung was not a transudate; it appeared to be associated with infection in the lung and approached a definitely infected fluid of the empyema type, although it had not reached that stage. It certainly was not pus, but it seems as if it might well have been infected fluid.

There appears to be some question of aneurysm in this case, and I know that there is no report in the record of a Hinton test. I do not believe it was aneurysm. I assume that the test was not done or was negative.

DR. JOSEPH C. AUB: It was done and was negative.

DR. RICHARDSON: I suppose they gave him x-ray treatment as a last resort. It must have been a forlorn hope.

As I went over this story the first time, I did not quite gather the time relation. The patient apparently was well until a month prior to admission, and on the twenty-sixth hospital day he died. That means that he was sick for two months. To me this story is one of infection. I have to mention the possibility of aneurysm, but I do not believe that it was present. I believe that this man started off with pneumonia, which did not clear up, that he later had an infected pleura, with perhaps a localized empyema, that still later he had enough obstruction of the bronchus to cause collapse of the right lower lobe and that he ended up with an acute purulent pericarditis. In his heart, I believe that he had a calcareous aortic stenosis and also probably a good deal of calcium in the aortic arch. I do not believe that he had an aneurysm. In view of the length of the history, the anemia that I mentioned is consistent with chronic sepsis. The change in the blood picture in the last five days is difficult to explain, but it might have been an acute process turning

into a chronic condition, perhaps as a result of drug therapy. I have nothing more to say.

I should like to have Dr. Robbins comment on the x-ray films. I might ask him first if he knows the answer; then I shall know how to interpret what he says.

DR. LAURENCE L. ROBBINS: I know the answer.

This is the film that was taken on admission, and all I can say is that the density of the right lower lung field could be due to fluid or to consolidation within the lung. The heart appears to be displaced to the right, and this shadow suggests widening of the superior mediastinum. At a later examination some of the density is definitely due to consolidation; I think, however, that there is still some evidence of fluid in the pleural cavity. The fact that we can see the bronchi suggests that there was a loss of aeration of the alveoli adjacent to the bronchi. Then as we go along a little farther, — if I remember correctly the department was being pushed for an opinion whether this could have been an aneurysm of the ascending aorta, — the process within the lung and the pleural cavity has cleared considerably. The heart and mediastinum remain considerably over to the right side. So far as we could determine at that time there was no widening of the aorta itself but the pulsations were considerably larger than one expects normally; we did not recognize the fact that there was some calcification in the valvular area. It is possible to see a large area of calcification in the region of the aortic valve. The heart has increased somewhat in size between these two examinations, representing a six-day interval. Even knowing the answer, I still cannot explain why the heart, mediastinum and aorta are displaced far to the right side. I do not believe that there is enough disease in the lung to explain this displacement.

DR. AUB: In the fluoroscopic examination the mass displaced to the right, which Dr. Robbins has stressed, pulsated twice in each beat, auricular and ventricular.

DR. RICHARDSON: I do not see much evidence of a localized empyema, but there may still be a localized area of infected fluid. My diagnoses are lobar pneumonia, which was resolving, calcareous aortic stenosis, acute pericarditis and possibly localized empyema.

DR. REED HARWOOD: The fact that this patient was sick for several weeks suggests that possibly he had something in the bronchial tree. Could he not have had a carcinoma of the bronchus to produce this bulge in the mediastinum?

DR. CHESTER M. JONES: Why did he have x-ray treatments?

DR. RICHARDSON: I was wondering about that.

DR. AUB: The patient had a thrill and a murmur as marked as any I have ever felt or heard. They extended almost to the right axilla and were much more marked when the patient was sitting up than

when he was lying down. That was the most striking thing about the examination.

He was first given sulfadiazine, which did not do any good, and then penicillin, which also was of no help; finally we had nothing else to offer except x-ray therapy, because of the remote possibility of Hodgkin's disease.

CLINICAL DIAGNOSES

Dissecting aneurysm, with rupture into pericardium.

Resolving pneumonia (Type 5).

Aortic stenosis.

Hemopericardium, with cardiac tamponade.

Massive pulmonary embolism, acute.

Thrombosis: right popliteal and femoral veins.

Resolving lobar pneumonia: right middle lobe.

Pulmonary infarct: left lower lobe.

Cardiac hypertrophy, left ventricular.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy this man presented an unusual picture. The heart was tremendous in size, weighing 800 gm., and showed marked left ventricular hypertrophy due to a marked calcareous aortic stenosis. Superimposed on the calcareous

FIGURE 2. *Mycotic Aneurysm of Aortic Valve Located between Aorta and Pulmonary Artery, Bulging into Right Ventricle and Rupturing into Pericardium.*

DR. RICHARDSON'S DIAGNOSES

Lobar pneumonia (resolving).

Calcareous-aortic stenosis.

Acute pericarditis.

Localized empyema?

ANATOMICAL DIAGNOSES

Calcareous aortic stenosis.

Subacute bacterial endocarditis, aortic valve, with formation of a mycotic aneurysm and rupture into pericardium.

stenosis was a subacute bacterial endocarditis that had eroded the aortic wall in two places, one just behind a cusp in a sinus of Valsalva and the other just above the valve and near a large calcareous mass. I wondered if the constant rubbing of the calcareous mass on the aortic intima in this location might have been an added factor in producing the rupture. The perforation opened into the space between the aorta and the pulmonary artery, producing a large mycotic aneurysm, 6 to 8 cm. in diameter, with a tremendous bulge into the right

ventricle just beneath the pulmonary valve (Fig. 2). The aneurysm had invaded the ventricular wall but had not reached the endocardium, and had the patient lived longer, it might have ruptured into the right ventricular cavity, forming an artificial interventricular septal defect. This large mycotic aneurysm had ruptured superiorly into the pericardium, which at the time of autopsy contained a liter of blood. That was not the immediate cause of death, although, if we had found nothing else, we might have interpreted it as such. The enlarged heart shadow seen on the roentgenogram several days before he died undoubtedly was produced by the hemopericardium. The immediate cause of death was a massive embolus that filled the entire pulmonary artery and had extended into several branches within the lungs. These emboli came from thrombi in the right popliteal and femoral veins.

The lungs showed resolving pneumonia of the right middle lobe and a recent infarct in the left lower lobe, which probably occurred after the last x-ray film was taken. Nonhemolytic streptococci were grown from the contents of the aneurysm, from the vegetation and from the blood at autopsy.

DR. RICHARDSON: I made the flatfooted statement that the blood was not consistent with subacute bacterial endocarditis. I should like to modify that remark. I think that the first blood picture was not that of chronic sepsis but of acute sepsis, consistent with the pneumonia; the later blood report could be consistent with subacute bacterial endocarditis.

DR. CASTLEMAN: I cannot be sure when the mycotic aneurysm began, but I believe that it was there the day the patient came into the hospital. It was probably not so large, but it almost certainly had begun. The initial infection that led to the bacterial endocarditis may well have been the upper respiratory one over a month before admission. The hemopericardium occurred slowly during the last days of his life.

CASE 31082

PRESENTATION OF CASE

A seventy-four-year-old woman was admitted to the hospital with abdominal cramps and vomiting.

The patient had been in fairly good health until two days prior to admission when, after a light meal, she was suddenly seized with generalized abdominal cramps. This was followed by an episode of vomiting, which relieved the pain. During the night a second attack occurred. The abdominal cramps continued, and she was unable to take anything by mouth without vomiting. During this period, several enemas were productive of hard fecal masses; there was a small spontaneous bowel movement about an hour before admission.

The patient had had a hernia in the left groin since the age of ten. It had never been painful. About thirty years before entry she had attempted to wear a truss, but it was unsatisfactory and soon abandoned. About twenty-five years before admission the patient had had an acute episode of nausea, vomiting and upper abdominal pain diagnosed as gall-bladder disease. She recovered after about two weeks. Since that time she had had mild intolerance to fried and fatty foods and had avoided them. She had never had jaundice or tarry or acholic stools.

The patient required three pillows for sleeping but had never had dyspnea or edema. She had been told that she had high blood pressure and had had an episode of severe epistaxis one year before entry. She had been blind in the right eye for a year and in the left eye for six months, as a result of cataracts.

Physical examination revealed an obese dehydrated woman, vomiting frequently. Bilateral cataracts were present. The lips were cyanotic. The lungs were clear. The heart sounds were faint and irregular, and there was a soft systolic murmur over the pulmonic area. The abdomen was moderately distended, tympanitic and diffusely tender; no peristalsis was heard. A mass the size of a goose egg was present in the left groin and was believed to be a femoral hernia; it was tender and not reducible. Varicosities were present on both legs.

The temperature was 99°F., the pulse 86, and the respirations 24. The blood pressure was 200 to 216 systolic, 90 diastolic.

Examination of the blood revealed a red-cell count of 5,300,000, with 90 per cent hemoglobin, and a white-cell count of 14,400. The urine had a specific gravity of 1.014, with a ++ test for albumin, a + test for acetone and no sugar; the sediment contained innumerable white cells. The serum non-protein nitrogen was 65 mg. per 100 cc., the protein 7.2 gm., and the chloride 93 milliequiv. per liter. The prothrombin time was 23 seconds (normal, 18 to 20 seconds).

A roentgenogram of the abdomen revealed numerous loops of dilated small intestine. There was a shadow of increased density overlying the sacrum (Fig. 1).

After several unsuccessful attempts, a Miller-Abbott tube was passed into the jejunum. The patient was given 6 cc. of Cedilanid intravenously. On the second hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD HAMLIN, JR.: Since Dr. McKittrick* has pointed out in a paper on acute intestinal obstruction that the one most important factor is the flat film of the abdomen, I think that we might start by looking at it.

*McKittrick, L. S. Diagnosis and management of acute obstruction of small intestine. *New Eng. J. Med.* 225:647-652, 1941.

DR. MILFORD D. SCHULZ: This film was made when the patient first came in, and you can see the widely dilated loops of small bowel. Over the sacrum is a shadow which, if it were in the right upper quadrant, I should call a gallstone. Since it is down over the sacrum I suppose it could be a calcified fibroid. If it were a gallstone I should expect some gas to be present in the liver or in the gall bladder.

in the opening sentence of the paper, "If one excludes strangulated external hernia, the diagnosis of which is easy and the treatment obvious. . . ." Sometimes the diagnosis is not so easy, and the treatment not so obvious.

But one must make a diagnosis. There are numerous factors that one would like to know about, as always in these exercises; some of them are probably

FIGURE 1.

DR. HAMLIN: There are obviously red herrings around, and that shadow is at least a fish.

DR. SCHULZ: It is interesting to know, too, that the gas stops at the dense shadow.

DR. HAMLIN: The diagnosis of small-bowel obstruction is obvious from the recorded physical examination and from the abdominal film. The story seems to lead rather clearly to a consideration of some sort of an incarcerated hernia as the cause of obstruction. Dr. McKittrick, as I mentioned before, in writing on intestinal obstruction, states

not incorporated in the record, but some of them may be. One certainly would like to know more about the history and the character of the pain. Was the pain constant, although crampy in nature? Had it become more persistent, with crampy exacerbations, indicating that perhaps some form of strangulation of the intestine was taking place? It is of tremendous importance to differentiate simple obstruction and strangulated obstruction.

DR. BENJAMIN CASTLEMAN: Dr. Crystal, can you answer any of Dr. Hamlin's questions?

DR. DEAN K. CRYSTAL: We gained the impression that it was crampy pain, the severity of which had not changed during the illness.

DR. HAMLIN: The description by the patient leads one to believe that she was not a good informant.

DR. CRYSTAL: It was rather difficult to get the story.

DR. HAMLIN: One would like to know about the physical examination. Diffuse tenderness was described. In a person as sick as this it is frequently difficult to determine more than the fact that the patient merely reacts to abdominal pressure, but no more in one area than in another.

One would like to know about the presence of microscopic blood in the stool; a guaiac-positive reaction would perhaps aid in making the diagnosis. Was an abdominal tap done? The presence of blood in the fluid removed by the passage of a small-lumen needle into the abdominal cavity is quite significant; a negative examination is of no value.

DR. CRYSTAL: The stools were guaiac negative. An abdominal tap was not done.

DR. HAMLIN: From the description of the physical examination one would be justified in drawing the conclusion that there was widespread peritoneal irritation. Diffuse tenderness is certainly suggestive, because in simple obstruction, unless the vomiting itself produces enough muscle tenderness, localization is usually rather narrow. It is perhaps unwise, however, to draw any conclusion as to that. Certainly the laboratory examinations do not add to the picture; in an elderly dehydrated patient the white-cell count is frequently increased, even more than this.

I am not at all clear whether or not this woman had peritonitis. I am inclined to say that she at least had peritoneal irritation.

We now come down to the origin of the intestinal obstruction, the aforementioned red herrings being present. The first and most obvious one is the tender, irreducible lump in the left groin. Were this the site of an incarcerated hernia causing obstruction with the period of time that had elapsed, — forty-eight hours, — one would expect strangulation to have occurred. One would also expect the patient to complain of pain in that particular area rather than of generalized abdominal cramps. Also since it is so obvious, I am inclined, on the basis of what generally turns up at these meetings, to discard it, at least temporarily.

Then we have the lovely red herring in the x-ray film — a 4-cm. spheroid mass containing calcium. at which point it appears that the dilated bowel stops. That is interesting indeed. We have a history of an attack twenty-five years previously, which is consistent with gall-bladder disease. The patient had an aversion to fatty and fried foods, which is also consistent with gall-bladder disease, and it is perfectly possible that she had, over a long period of time, gradually eroded away an adhesion between the gall bladder and the small bowel and passed a stone into the small intestine, where it lodged and

produced the obstruction. It is present on every film, but as Dr. Schulz has pointed out, it might also have been due to a calcified fibroid.

What are the other possibilities of small-bowel obstruction? At this patient's age, with the obvious heart condition that she had, — hypertension for a long period of time, — one must consider vascular occlusion in the mesentery of the small bowel, either embolism or thrombosis. If one tried to fit that into the story as given, I believe that it would be easier to ascribe the accident to thrombosis than to embolism. Although the onset was sudden, one gets the impression that she gradually became worse and that the degree of illness on entry was more attributable to the electrolyte imbalance and loss of fluids in general than to anything else.

There are a number of other things that can produce this picture, — volvulus, tumor and adhesions, — but I do not believe that we have to consider them as closely as the first three that I have mentioned, namely, hernia, gallstone ileus and vascular accident. There are many things against a vascular accident: the patient did not complain of pain in the back, she had a negative guaiac test on the stool, and there was no other evidence of blood. I eliminate the hernia on the basis of lack of marked tenderness. Was any history obtained regarding a change in the appearance of this mass in the left groin?

DR. CRYSTAL: There was no change in appearance. She said that it was more tender in the region of the hernia than it had been before the onset.

DR. HAMLIN: That does not help.

I must stick to one thing, and since the apparent gallstone appeals to me, I am going to call this gallstone ileus. I am sure that the surgeon hoped that that was the diagnosis. It is a relatively infrequent condition, and a rather satisfactory one to operate on.

DR. CHESTER M. JONES: Where is the gallstone in gallstone ileus usually found?

DR. HAMLIN: Usually in the lower third of the ileum. Here, it could be close to the terminal ileum. From the story and certain deductions that can be drawn from the films it appears that the major part of the small bowel was affected by the obstruction.

CLINICAL DIAGNOSIS

Gallstone ileus?

Incarcerated femoral hernia?

DR. HAMLIN'S DIAGNOSIS

Gallstone ileus.

ANATOMICAL DIAGNOSIS

Gallstone ileus.

PATHOLOGICAL DISCUSSION

DR. CRYSTAL: We thought that the condition was either a gallstone ileus or an incarcerated hernia. If the former, we considered that operation was contraindicated because of the duration and the patient's age. We did think, however, that it was

worthwhile to subject her to a less serious procedure and gambled on the hernia. She had a hernia, which was incarcerated but not strangulated, with viable omentum. We later operated and found that she had a gallstone of about the expected size. The bowel had no necrosis around it. It was only necessary to make a slit over the stone, deliver it and close the bowel. It was an extremely gratifying operation.

DR. BENJAMIN CASTLEMAN: How far was the tip of the Miller-Abbott tube from the stone?

DR. CRYSTAL: It was within 15 or 20 cm.

DR. HAMLIN: So the stone held tightly.

DR. CRYSTAL: Apparently not, and for that reason we did not use the maneuver of moving the stone back several centimeters rather than cutting into area that had undergone damage. Since the bowel

was in good condition there appeared to be no indication for moving the stone.

DR. CASTLEMAN: The operation is a lot easier with the Miller-Abbott tube in place?

DR. HAMLIN: A word might be said about that. In the article that I have previously mentioned, Dr. McKittrick points out that the danger of operation on simple obstruction, without obvious strangulation but with distention of the bowel, is much greater than taking the chance that there may be strangulation and resultant perforation; delay in order to deflate the bowel with a Miller-Abbott tube in obstruction over twenty-four hours old is almost mandatory.

DR. CASTLEMAN: That is the point I wanted to bring out.

Correction. Perusal of the published record of Case 30521, which appeared in the December 28, 1944, issue of the *Journal*, made me suddenly

plicating posterior myocardial infarction or a complicating acute cor pulmonale, or both, superimposed on a myocardial infarction that was obvious both

FIGURE 2. Electrocardiograms. A was taken on the day of admission; B, on the third hospital day; and C, on the fifth hospital day.

aware of an error in Figure 2, which presented three electrocardiograms taken, respectively, on the day of admission, on the third hospital day and on the fifth hospital day. As had been noted in the protocol of the case and in my own discussion, there was a striking difference between the second electrocardiogram and the first and third tracings. This had, at first, seemed to fit the possibility of a com-

by history and electrocardiogram and was evidently anterior in position. There was no posterior myocardial infarction found at autopsy, however, and a possible cor pulmonale resulting from a complete obstruction by an interauricular thrombosis of the right pulmonary veins as they entered the left auricle, and gross infarction of the right lung, should have been apparent at the time of admission, when

x-ray evidence of massive involvement of the right lung was already clear. Thus, the confusing change in the electrocardiogram was difficult to explain on the basis of both the clinical and the post-mortem findings.

A closer inspection of the electrocardiographic records revealed at once the probable error that had crept in to cause this confusion. A glance at Figure 2 as published and Figure 2 as corrected, both of which are presented herewith, shows the probability, in fact almost certainty, that in the strip (B) taken on the third hospital day, the original Lead 1 should have been labeled Lead 2, that Lead 2 should have been labeled Lead 1 and that Lead 3 is upside down. This can readily be accounted for by the transposition of the left-arm and left-leg wires, which is less frequent and also more easily overlooked than the error of transposing the arm wires, which results in an inversion of Lead 1, with a switch of Leads 2 and 3. Also, of course, in this record, Lead CF₄ becomes Lead CL₄, since it was the left arm, and not the left leg, that was connected with the chest electrode.

The error in the precordial lead is slight, but that in the limb leads becomes extremely significant.

There is no longer a Q wave in Lead 3 and only a small Q wave in Lead 2, whereas the prominent Q wave in Lead 1, also found in the next electrocardiogram, is perfectly consistent with a gross anterior myocardial infarct, as is also the inversion of the T wave in that lead. Although there was no observation at the time of taking this record of the error in the placing of the lead wires, the fact that the electrocardiogram was not taken in the routine work of the Cardiac Laboratory, as well as the confusing picture that resulted and has been explained above, makes it quite certain that an error of technic was responsible for what had seemed like a curious and complicated picture in the electrocardiographic pattern. Thus, the second paragraph of my own discussion of this case, found on page 888, can be completely omitted, with but slight revision of the first paragraph.

Finally, this error and the necessary correction are another example of the constant need of everlasting vigilance in the interpretation of electrocardiograms; one should be particularly on the lookout for the very errors in technic that occurred here. We ourselves have constantly preached about this and yet have here been guilty of the same offense.

POSTWAR PLANNING

In an editorial carried in the August 31 issue, the *Journal* visualized "a postgraduate medical education program of unprecedented proportions—something that will have to bring into use a larger proportion of clinical material than has ever before been utilized." Under the date of November 9, the Committee on Medical Education and Hospitals of the American Medical Association has addressed a request for information to all hospitals approved for internship and residency, enclosing a copy of a recent report,* in which it was shown that "opportunities for graduate training in surgery, obstetrics-gynecology, otolaryngology and ophthalmology will

*Johnson, V., and Arestad, F. H. Educational facilities required for returning medical officers. *J. A. M. A.* 126:253-257, 1944.

probably need to be doubled in number while facilities in urology, internal medicine, orthopedics, pediatrics, pathology, radiology, psychiatry and neurology may require an increase of 30 to 70 per cent."

It is conceivable that these increased opportunities may be devised, as and when the war ceases to preoccupy many of the most vigorous and educationally effective members of the profession, thus permitting them to return to peacetime bedsides and operating rooms. Until this is possible, however, it is unrealistic to expect any great expansion of teaching activity. In the request for information referred to above it is stated that training courses in industrial medicine and general medicine will be called for. These are large subjects, having more in common with general practice than they do with the orthodox type of specialty, and they should be made as attractive as possible, since the relative distribution of workers in special and general fields needs sharp adjustment if the people are to be most advantageously served in the future. Up to 1944, for example, more otolaryngologists than internists had been certified and there were nearly as many radiologists as there were surgeons.

In the report, particular attention is called to the fact that there is a major time discrepancy between the courses now available and those that it is estimated will be demanded. Thus, over 90 per cent of the opportunities for postgraduate training in 1943-1944 were in courses of about one month's duration, whereas it is estimated that only 7 per cent of the postwar demand will be for such short courses. How can these longer courses be organized? Here, in prospect, are some thousands of candidates for training—training that will require a greater number of residencies than are now in or readily put into commission on a modern basis. These candidates will tend to compete with one another for the better opportunities, and this competition will, in turn, tend to make of the opportunities themselves a marketable commodity. There is therefore a real need for some sort of supervision by recognized and competent authorities, such as the American Medical Association, the surgeons general of the United States Army, Navy and Public Health Service, the American and the Catholic

hospital associations, the American colleges of Surgeons and of Physicians, the boards in the medical specialties, the medical schools, the state licensing boards and medical societies, the Veterans Administration and perhaps many other interested groups. It is good to know that the Massachusetts Medical Society now has a Postwar Planning Committee actively studying the means by which it may be of help in this great task.

DIABETES — A NEGLECTED DISEASE — AND WHAT SHOULD BE DONE ABOUT IT

DIABETES is a neglected disease when compared with tuberculosis or infantile paralysis. Diabetic patients equal in number those with tuberculosis and are four times as numerous as those crippled with infantile paralysis. Yet, contrast the organizations devoted to the control and eradication of tuberculosis throughout the United States and the huge sums raised to combat the disease, as well as the \$11,000,000 or more collected for the study and care of cases of infantile paralysis, with the one small national and the four recently created local organizations devoted to diabetes.

The need for an aroused interest in diabetes is growing, because each year the number so afflicted is sure to increase. It is a disease of middle adult life, and the population of the country is steadily advancing to that decade, forty-five to fifty-five years, in which the onset of diabetes is most frequent. Diabetic patients themselves are contributing to the gain in numbers because they are living, on the average, three times as long as they did before the introduction of insulin. Furthermore, increased medical supervision and improved vital statistics are revealing more cases.

Notwithstanding the availability of insulin, many patients still die needlessly of diabetic coma. This could be remedied in a large degree if each hospital in the country would plan and equip itself for the efficient treatment of diabetic emergencies. The time required and the capital involved for equipment would be minimal, and the costs for available

services of laboratory personnel at night and on Saturday afternoons, Sundays and holidays would be insignificant compared with that incurred for maintaining operating rooms during those same periods. Indeed, a hospital that does not exercise such foresight in the not distant future may be held derelict to its local needs.

The discovery of alloxan diabetes has opened up opportunities for research never before even dreamed of, and these new pathways of investigation should be exploited. Already, in less than a year and a half following the report of Shaw Dunn's original work, the results of experiments with alloxan have been published from eight different countries.

To treat the rapidly growing number of diabetic patients, to protect them in their emergencies and complications and to foster research, funds are needed, and the most readily available source is from the patients themselves. They constitute an intelligent group and are able and ready to contribute if asked. They are not content with the present methods of treatment. They know that research gave them insulin, and they want to provide for more research to improve present methods of treatment. They are painfully aware of the shortage of hospital beds, not simply for routine care but even for the serious complication of the disease. They appreciate that fellow patients are dying needlessly of diabetic coma because of their lack of a diabetic education or because of inferior medical treatment. They know that diabetes is hereditary, and they wish to protect their families, just as their relatives wish to avoid diabetes. All diabetic patients and their relatives in any community should be asked to furnish the funds for facilities in their local hospital to protect them in emergencies and to promote research in hospitals that are properly qualified. They rightly look on such gifts as personal insurance.

Physicians in the United States should raise \$10,000,000 in 1945 for the creation of diabetic funds and for the betterment of hospital facilities. If this is not done, they, too, can be held derelict, because patients and their relatives are more than ready to give the money to improve the care of the diabetic patient.

MASSACHUSETTS MEDICAL SOCIETY

The *Journal* lacks extra copies of the January 13, April 6, May 11, June 1 and July 27, 1944, issues. Many requests have been made by libraries and other subscribers who wish to bind Volumes 230 and 231 but who did not receive those particular issues. If any subscribers who do not bind their copies have the above-mentioned issues on hand, the *Journal* will gladly pay 15 cents for each copy left at or mailed to its office (8 Fenway, Boston 15).

MASSACHUSETTS DEPARTMENT
OF PUBLIC HEALTHDEFIBRINATED HORSE BLOOD
FOR LABORATORY USE

For a good many years the Antitoxin and Vaccine Laboratory of the Massachusetts Department of Public Health has been furnishing defibrinated horse blood to various laboratories in the Boston area. As with other products, this has been a free service. In the past, the service has been limited to those who could have the blood picked up by messenger, since no evidence was available that the blood would withstand shipment by mail at all seasons.

Recently there has been an increased demand from hospitals and laboratories in other parts of the Commonwealth for this service. During the past summer a supply of such blood has been mailed to several such laboratories with gratifying results. The blood has arrived in good condition and has obviated the need for bleeding a person or animal for a few red cells every time a batch of culture medium is prepared.

It is now planned to make this service available to all the hospitals and laboratories of the Commonwealth. The requirements are that such institutions return promptly the empty containers for further use and that they gauge their needs so that a minimum of blood will be wasted. Hospitals and laboratories that are placed on the mailing list may receive up to 200 cc. of defibrinated blood at intervals of two weeks. This will ensure a continuous supply of usable blood, since it can be kept in satisfactory condition for this period if properly refrigerated.

Inquiries should be addressed to the Antitoxin and Vaccine Laboratory, 375 South Street, Jamaica Plain 30, attention of Dr. J. A. McComb.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Textbook of Gynecology. By Emil Novak, M.D., associate in gynecology, Johns Hopkins University School of Medicine, and gynecologist, Bon Secours and St. Agnes hospitals, Baltimore. Second edition. 8°, cloth, 708 pp., with 456 illustrations. Baltimore: William and Wilkins Company, 1944. \$8.00.

This second edition of a textbook first published in 1941 has been thoroughly revised and brought up to date, which necessitated a complete resetting of the text. Many new original illustrations, including a considerable group of color photographs, have been added. Two new chapters, covering the embryology of the female generative organs and the female urologic conditions that are of special interest to the gynecologist, are included. The work has been written primarily for students and general practitioners, and for this reason details of operative technic have been omitted.

An Introduction to Public Health. By Harry S. Mustard, M.D., LL.D., director and professor of public health practice, Delamar Institute of Public Health, College of Physicians and Surgeons, Columbia University, New York City. Second edition. 8°, cloth, 283 pp. New York: Macmillan Company, 1944. \$3.25.

The first edition of this manual was written in 1935, and this new edition has been completely revised and brought into conformity with modern practice in the public-health field. Two chapters, one on industrial hygiene and the other on medical care, have been added, and the morbidity and mortality data reflect the latest available statistics. The volume is designed for use in all introductory courses in public health whether in schools of public health, in medical schools, in nursing schools or in colleges.

Our Concern — Every Child: State and community planning for wartime and postwar security of children. By Emma O. Lundberg. Children's Bureau, Publication 303. 8°, paper, 84 pp. Washington: Government Printing Office, 1944. 15 cents.

This pamphlet discusses in an abbreviated form the welfare of children in peace and in war from the viewpoints of both the state and the community. It provides outlines for planning services in all their aspects for the welfare of children.

Malaria: Its diagnosis, treatment and prophylaxis. By William N. Bispham, M.D. 8°, cloth, 197 pp., with 4 plates and frontispiece. Baltimore: Williams and Wilkins Company, 1944. \$3.50.

This small book has been written to give the physician a knowledge of the clinical features of malaria. It considers etiology, symptomatology, diagnosis, pathology, treatment, prevention and immunity. Blackwater fever is briefly discussed. The final chapter is on prevention and treatment of malaria in West Africa and is contributed by Dr. L. T. Coggeshall. The first two chapters comprise a short history of malaria and its geographic distribution. A good index makes all material available, and this manual should be useful as a reference source.

Plaster of Paris Technic. By Edwin O. Geckeler, M.D., associate professor of orthopedic surgery and chief of the Fracture Service, Hahnemann Medical College and Hospital, Philadelphia. 8°, cloth, 220 pp., with 208 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$3.00.

Unusually well illustrated and suitable for the instruction of graduate and undergraduate students, the text gives a

practical working knowledge of the everyday conditions in which plaster of Paris may be used. There are special chapters on its use in war surgery and in the treatment of burns.

Strophonthin: Clinical and experimental experiences of the past twenty-five years. By Bruno Kisch, M.D. 8°, cloth, 158 pp., with 24 illustrations. New York: Brooklyn Medical Press, 1944. \$4.00.

This monograph has been written for the purpose of urging the American medical profession to reconsider the question of the clinical application of strophonthin. In his text the author embodies conclusions derived from a number of experiments on animals and records his clinical observations, particularly those on how the drug affects the vagus nerve and on how the extrasystoles should be judged after strophonthin administration. A comprehensive review of the literature of the past twenty-five years has been appended to the text. The book is well printed, with a good type on good paper.

The Blood Pressure and Its Disorders including Angina Pectoris. By John Plesch, M.D. (Budapest), M.D. (Berlin), L.R.C.P. and S. (Edin. and Glas.). 8°, cloth, 149 pp., with 61 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$4.50.

This small manual discusses arterial and venous blood pressures, with particular reference to angina pectoris.

Fertility in Women: Causes, diagnosis and treatment of impaired fertility. By Samuel L. Siegler, M.D., attending obstetrician and gynecologist, Brooklyn Women's Hospital, attending gynecologist, Unity Hospital, assistant obstetrician and gynecologist, Greenpoint Hospital, and consultant in gynecology, Rockaway Beach Hospital. With a foreword by Robert L. Dickinson, M.D. 8°, cloth, 450 pp., with 194 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$4.50.

The various aspects of abnormal and impaired fertility are discussed from a systemic or functional point of view. There is a long chapter on the physiology of the female sex cycle and the various methods for evaluating its efficiency. Considerable space is devoted to both general and specific therapy, to the treatment of ovarian imbalance and to the faulty reception of spermatozoa.

Manual of Psychological Medicine for Practitioners and Students. By A. F. Tredgold, M.D., F.R.C.P., F.R.S.E., consulting physician, University College Hospital, London, and lecturer on mental deficiency, London University. 8°, cloth, 298 pp. Baltimore: Williams and Wilkins Company, 1945. \$5.00.

This small book is essentially a manual on disorders of the mind for the use of all those who are brought into contact with military personnel.

The Diseases of the Endocrine Glands. By Herman Zondek, M.D. (Berlin), director of the Medical Division, Bikur Cholim Hospital, Jerusalem. Translated by Carl Prausnitz Giles, M.D. (Breslau), M.R.C.S. (Eng.), L.R.C.P. (Lond.). Fourth (second English) edition. 8°, cloth, 496 pp., with 180 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$11.00.

The first edition of this book was written in 1935, and the present edition has been revised to embody important results of recent researches.

Manual of Military Neuropsychiatry. Edited by Harry C. Solomon, M.D., professor of psychiatry, Harvard Medical School, and medical director, Boston Psychopathic Hospital,

and Paul I. Yakovlev, M.D., clinical director, Walter E. Fernald State School, and instructor of neurology, Harvard Medical School. 12°, cloth, 746 pp., with 15 illustrations. Philadelphia and London: W. B. Saunders Company, 1944. \$6.00.

This manual is intended as a reference text on topics of clinical neurology and psychiatry and has been prepared especially for medical officers, often remote from libraries and textbooks. The book is divided into six parts: history of neuropsychiatry during World War I and general organization during the current war; induction (having to do with the screening and examination of inductees); administration and disposition; clinical entities; prophylaxis and therapy; and special topics.

Secretory Mechanism of the Digestive Glands. By B. P. Bahkin, M.D., D.Sc., LL.D., research professor of physiology, McGill University, Montreal. 8°, cloth, 900 pp., with 220 illustrations. New York: Paul B. Hoeber, Incorporated, 1944. \$12.75.

This new book on the physiology of the digestive glands embodies the work performed by the author and his co-workers during the last fourteen years in the Department of Physiology of McGill University. It is not monographic in scope, since no attempt has been made to review the whole of the literature concerned with the secretory function of all the digestive glands. The book deals mainly with the mechanisms regulating secretory activity, as exemplified in particular by the functions of the gastric, salivary and pancreatic glands. So far as possible, the author has included in his work the more important facts known in regard to the secretory functions of the digestive tracts up to the present date. An extensive bibliography is appended to the text.

The Radiology of Bones and Joints. By James F. Brailsford, M.D., Ph.D., F.R.C.P., F.I.C.S., Hunterian professor, Royal College of Surgeons, England (1934-1935 and 1943-1944), radiological demonstrator in living anatomy, University of Birmingham, radiologist to St. Chad's Hospital, the City of Birmingham Infant Welfare Centres and the Military Hospital, Hollymoor, Birmingham, and consulting radiologist to the City of Birmingham Hospitals, the Robert Jones and Agnes Hunt Orthopaedic Hospital, the Birmingham Accident Hospital and Rehabilitation Centre and the Birmingham Mental Hospital. Third edition. 8°, cloth, 440 pp., with 404 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$12.00.

Ten years have elapsed since the publication of the second edition of this special work, first published in 1934. The book now represents an analysis of the work of the author during the past twenty-five years. The present edition gives a more comprehensive account of the variations of the normal developmental and the pathologic conditions in bones and joints than was possible in the earlier editions. Particular attention has been paid to the changes in bones and joints resulting from trauma, the osseous dystrophies, tuberculosis, syphilis and neoplasms. The treatment of certain conditions has been considered in the light of radiographic findings. An extensive bibliography is appended to the text. The type and paper are good, and there are many full-page radiographic plates.

Diseases of the Digestive System. Edited by Sidney A. Portis, M.D., associate professor of medicine, University of Illinois (Rush) Medical School, attending physician, Michael Reese Hospital, consulting physician, Cook County Hospital, and

consultant in medicine, Institute of Psychoanalysis, Chicago. 8°, cloth, 932 pp., with 182 illustrations. Philadelphia: Lea and Febiger, 1944. \$11.00.

This second edition of an authoritative work by fifty contributors has been completely revised and reorganized to meet the needs of students and teachers in the field. Special emphasis has been placed on the psychosomatic aspects of gastrointestinal symptoms. The chapters have been rearranged, placing the physiology of each organ before its clinical discussion. Each contributor has considered the effects of emotional stimuli on the gastrointestinal tract. The chapter on psychosomatic disturbances has been enlarged. Selected references have been appended to each chapter.

Recent Advances in Anaesthesia and Analgesia, including Oxygen Therapy. By C. Langdon Hewer, M.B., B.S. (Lond.), D.A. (Eng.), senior anaesthetist, St. Bartholomew's Hospital and St. Andrew's Hospital, Dollis Hill, anaesthetist, Brompton Chest Hospital and Emergency Medical Service, and consulting anaesthetist, Mid-Herts and West-Herts hospitals. Fifth edition. 8°, cloth, 343 pp., with 141 illustrations. Philadelphia: Blakiston Company, 1944. \$5.50.

In this edition it has been possible to include new material on a large number of important subjects. Each section has been carefully revised throughout, and attention has been given to the military aspects of anesthesia. An additional chapter on anesthetic charts and records has been placed at the end of the book. To each chapter has been appended a selected list of references.

The Urinary Tract: A handbook of roentgen diagnosis. By H. Dabney Kerr, M.D., professor of radiology, State University of Iowa College of Medicine; and Carl L. Gillies, M.D., associate professor of radiology, State University of Iowa College of Medicine. 8°, cloth, 320 pp., with 120 illustrations. Chicago: Year Book Publishers, Incorporated, 1944. \$5.50.

The objective of this small handbook is to provide student, practitioner, urologist and radiologist with selected plates of the commoner and some of the uncommon lesions of the urinary tract. The plates are of cases studied radiographically at the University of Iowa hospitals. All reproductions show the structures at about a third of the actual size, and no retouching has been done on the negatives. In every case illustrating pathologic involvement, the hospital record of the patient has been examined and the diagnosis has been based to a large extent on the study of all available information. Whenever possible, several examples of each condition have been included, because of the fact that no two normal structures or no two lesions appear exactly alike. The text is divided arbitrarily into sections on the kidneys, ureter, bladder and urethra.

Freud's Contribution to Psychiatry. By A. A. Brill, Ph.B., M.D. 12°, cloth, 244 pp. New York: W. W. Norton and Company, Incorporated, 1944. \$2.75.

The author presents an intimate evaluation of the development of psychoanalysis as he himself lived through it, emphasizing the statements with appropriate quotations from his extensive correspondence with Freud. Dr. Brill was one of the pioneers of psychoanalysis and since 1907 has devoted

all his time to the study and dissemination of Freud's teachings. He was Freud's first English translator, his most active expositor in this country and his most ardent co-worker and close friend.

Foster Home Care for Mental Patients. By Hester B. Crutcher, director of social work, State of New York Department of Mental Hygiene. 8°, cloth, 199 pp. New York: The Commonwealth Fund, 1944. \$2.00.

The author discusses the meaning and the objectives of family care, its development in the United States and foreign countries, some of the results achieved, the financial as well as the therapeutic advantages, various procedures, including selection and supervision of cases, and forms for keeping the necessary records. Foster-family care is care under hospital supervision of mentally ill persons or mental defectives in families other than their own. It is not mere custody but therapeutic care under the supervision of the mental hospital. It is a recent development in the United States.

The Medical Clinics of North America. Boston Number: September, 1944. 8°, cloth, 263 pp., illustrated. Philadelphia: W. B. Saunders Company, 1944. \$3.00.

NOTICES

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, March 1, in the classroom of the Nurses' Residence at 7:15 p.m. The topic will be "Selection of Hypertensive Patient for Sympathectomy." Dr. Dera Kinsey will be chairman.

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

- Friday, March 2 — The Significance of the Eosinophil Count in Acute Infections. Dr. Francis C. Lowell.
- Wednesday, March 7 — Dental Medicine. Dr. Robert W. Buck.
- Friday, March 9 — Protein Nutrition in Problems of Medical Interest. Dr. Fredrick J. Stare.
- Wednesday, March 14 — The Glaucoma Problem and General Medicine. Dr. Joseph Igersheimer.
- Friday, March 16 — Protolytic Enzymes in Tissues. Dr. Paul C. Zamecnik.
- Wednesday, March 21 — The Diagnosis of Diabetes Mellitus. Dr. Joseph Rosenthal.
- Friday, March 23 — Some Aspects of Cardiac Surgery. Dr. Robert E. Gross.
- Wednesday, March 28 — The Surgical Gallbladder. Dr. Leland S. McKittrick.
- Friday, March 30 — Graphic Methods and Auscultation of the Heart. Dr. Aldo A. Luisada.

On Monday mornings (except March 12) clinics will be given by Dr. Samuel Proger. On Tuesday and Thursday mornings Dr. S. J. Thannhauser will give medical clinics on hospital cases. On Saturday mornings clinics will be given by Dr. William Dameshek.

SEVENTY-FIVE YEARS OF PUBLIC HEALTH IN MASSACHUSETTS

MERRILL E. CHAMPION, M.D.*

BOSTON

THE seventy-fifth anniversary of the founding of the State Board of Health of Massachusetts calls to mind certain outstanding personalities and their relation to the development of public-health theory and practice in the Commonwealth. Most of these—though not all—were medical men; some of them were distinguished as well in fields other than that of public health. It is the purpose of this article to trace the origin and development of the public-health movement in Massachusetts and to discuss the part played by outstanding men who guided it through the years since 1869.

LEMUEL SHATTUCK, PIONEER

The first to appear on the public-health horizon in this state, of those whose impress was an indelible one, was Lemuel Shattuck. Although bearing a name now famous for its medical connotations, Shattuck was not medically trained, but was first a schoolteacher and later a publisher and bookseller. He early became interested in subjects that are now generally included in the scope of public health. He it was who broke the ground and sowed the seed that many years later produced the first permanent state board of health in America. Shattuck began by obtaining the passage of an act on which is based the present system of birth and death registration in this state. In 1849, he helped to secure the passage of legislation providing for a sanitary survey of the Commonwealth and served as a member of the commission appointed for that purpose. The report of the commission appeared in 1850 and is an extraordinary document, even today, in the light of seventy-five years of rapidly increasing knowledge and experience. The caliber of the thinking exhibited in it may be gathered from the following quotation:

We believe that the conditions of perfect health, either public or personal, are seldom or never attained, though attainable; that the average length of human life may be very much extended, and its physical power greatly augmented; that in every year, within this commonwealth, thousands of lives are lost which might have been saved; that tens of thousands of cases of sickness occur which

might have been prevented; that a vast amount of unnecessarily impaired health and physical debility exists among those not actually confined by sickness; that these preventable evils require an enormous expenditure and loss of money, and impose upon the people unnumbered and immeasurable calamities, pecuniary, social, physical, mental and moral, which might be avoided; that means exist, within our reach, for their mitigation or removal; and that measures for prevention will effect infinitely more than remedies for the cure of disease.

Nearly all the general aspects of present-day health practice are at least foreshadowed in the Shattuck report. As a sampling of the quality and scope of the committee's recommendations one may refer to these: the establishment of a general board of health; increasing the number of effective local boards of health; census of the population; registration of births, marriages and deaths; sanitary surveys; study of sickness in schools; tenements for the laboring classes; quarantine regulations; periodical and special vaccinations; abatement of the smoke nuisance; and many others, some of which have not even yet received adequate attention.

HENRY I. BOWDITCH, ORGANIZER

A period of twenty years followed the presentation of this report, during which the Legislature did nothing to further the objectives of the Shattuck report. Another outstanding figure then appeared in the person of Henry Ingersoll Bowditch. Dr. Bowditch, after graduating from Harvard Medical School in 1832, studied in France under the famous Louis. A characteristic of the latter was his insistence on statistical proof as an aid in estimating the value of the various forms of medical treatment. It is perhaps not too farfetched to suppose that this kind of training influenced Bowditch in his later devotion to the cause of public health in Massachusetts. Bowditch had an independent mind and was not afraid to propose new measures even in the face of disapproval on the part of medical colleagues. He was a man of standing and influence at the time when the State Board of Health was established; he was known for his work on tuberculosis, and had been professor of clinical medicine at Harvard Medical School.

*Formerly Chairman, Division of Hygiene, Massachusetts Department of Public Health.

As a result of energetic effort on the part of Dr. Bowditch and like-minded people and, it is said, because of an outbreak of typhoid fever that aroused fear in the minds of certain legislators, Lemuel Shattuck's project at last took form, and a state board of health was created by act of the Legislature in 1869. Dr. Bowditch was chosen chairman of this board. The statute that started the new board on its long and honorable course has often been quoted but will bear repetition. It reads as follows:

The Board shall take cognizance of the interests of the life and health of the citizens of this commonwealth. They shall make sanitary investigations and inquiries in respect to the causes of disease, and especially of epidemics and the sources of mortality, and the effects of localities, employments, conditions and circumstances upon the public health; and they shall gather such information in respect to those matters as they may deem proper for diffusion among the people. They shall advise the government in regard to the location and other sanitary conditions of any public institutions, and shall report to the Legislature each year with such suggestions as to legislative acts as they deem necessary.

For ten years, Bowditch remained the main-spring of the State Board of Health, ably seconded by two secretaries of the Board, Dr. George Derby, who died in office in 1874, and his successor, Dr. C. F. Folsom. These ten years were years of real pioneering in the virgin field of public health. The activities of this period have been well summarized by Whipple¹ in these words:

The Massachusetts State Board of Health was studying Massachusetts, her people and their health, the diseases common among them, the sanitation of their homes, the nuisances to which they were subjected, the water they drank, the method of waste disposal, the ventilation of their school houses, the disposal of their dead. The Board was "taking cognizance of the interests of health and life."

STRANGE INTERLUDE

In 1879, politics reared its ugly head. General Ben Butler was fulminating against what he termed the numerous commissions that were "spending wastefully the people's money." Those in charge of the government at that time thought to avoid trouble by a little appeasement. The State Board of Health was merged and at least partly submerged in the State Board of Health, Lunacy and Charity. Dr. Bowditch soon resigned in protest.

In the midst of the tribulations of the triple-headed board, a new figure appeared as a worthy successor to Dr. Bowditch. This was Dr. Henry Pickering Walcott, who was later to reach the stature of "a great sanitary statesman." Dr. Walcott joined the Board of Health, Lunacy and Charity in 1880 as executive for its health committee. Two years later he resigned this position to become chairman of the committee. He remained in charge of the State's health activities for thirty-two years.

HENRY P. WALCOTT, SANITARY STATESMAN

It is hard to appraise the full value of the work of a man like Henry P. Walcott. Always an austere

and dominant personality, he nonetheless was able to work with other strong men. A noteworthy example of this was his long association with the engineer, Hiram F. Mills, who shared with Walcott much of the credit for the Board's accomplishments during twenty-eight years, the services of both men ending with the reorganization of the Board in 1914.

It seems, in retrospect, as though Dr. Walcott's strength lay in an ability to take a broad view of the whole field of public health, to appreciate the value of new discoveries and to keep clearly in mind the proper relations of state to local communities. During his long administration occurred some of the great advances in public-health knowledge. These were at once absorbed by the Massachusetts State Board of Health and put to work. Many of these contributions to knowledge originated with the state organization itself. An example of this at once comes to mind in the research work of the Lawrence Experiment Station and the construction of the Metropolitan Water and Sewerage systems.

The Lawrence Experiment Station was planned by Mills in 1887 and represented a great advance in the possibilities of the sanitary control of the environment. It has been said, "The investigations at the Lawrence Experiment Station laid the foundation for the scientific treatment of sewage and have given the initiative for similar investigations in this and other countries."² In 1893, a sand-filtration plant for the purification of the water supply of the city of Lawrence was built after plans by Mills. The saving of lives brought about as a result of these and similar engineering accomplishments can hardly be overestimated. The period covered by the life of the State Board of Health from 1869 to 1914 may truly be called the era of sanitary engineering, and of this era two of the outstanding promoters were Walcott and Mills.

There were other well-known figures as well whose work centered in the State Board of Health during that period. Only passing reference can be made to them here. The first in point of time was Dr. Samuel Abbott, secretary of the Board from 1886 to his death in 1904. His report "Vital Statistics in Massachusetts from 1856 to 1895" was a striking piece of work. It may be found in the 1896 report of the Board. The second, Dr. Theobald Smith, had, of course, an international reputation quite apart from his services with the Board. He came to Massachusetts in 1895 as director of the recently established Antitoxin Laboratory. The production and distribution of diphtheria antitoxin represented a new service to Massachusetts physicians and their patients — a type of service that has been steadily extended since then. The Bacteriological Laboratory, too, starting at that time modestly under the State Board of Health, has, through the devoted service of its present chief and her associates, become indispensable to thousands of physicians throughout the Commonwealth. The

Wassermann Laboratory, although established later, in 1915, should be referred to here. It also has grown amazingly in activities and usefulness.

Dr. Smith resigned the directorship of the Antitoxin Laboratory in 1914 and was succeeded by Dr. Milton J. Rosenau, whose great reputation, like that of Dr. Smith, came from research, teaching and writing. Dr. Rosenau held the directorship until 1920.

Before turning from the State Board of Health to its successor, two other secretaries of the Board must be mentioned. Dr. Charles Harrington served from 1905 to 1909, at the same time serving as professor of hygiene at Harvard Medical School. He was succeeded by Dr. Mark Richardson, who ably carried on the work until the Board was reorganized in 1914.

THE DEPARTMENT OF HEALTH

The year 1914 marks a great change in state health administration in Massachusetts. The State Board of Health had done a magnificent piece of work with the older type of setup, but a different kind of administrative plan was beginning to be popular. Instead of unpaid boards with paid secretaries, states were turning to a single-headed department, with a full-time commissioner and a part-time advisory council, the latter having no executive authority. This kind of health department was proposed to the Massachusetts Legislature and after much discussion the bill was passed. America's first fully functioning state board of health came to an end and was succeeded by the State Department of Health. The man who did the most to get through the Legislature the bill providing for this department was Dr. Enos H. Bigelow, afterward president of the Massachusetts Medical Society, who was at the time a member of the Legislature.

ALLAN J. McLAUGHLIN AND HIS STAFF

It goes without saying that the prime necessity in getting a new enterprise started is the right kind of person to head the organization. Massachusetts was most fortunate in getting just such a one in Dr. Allan J. McLaughlin. A man of forceful personality and extremely wide experience in public health, he had the executive ability necessary for rebuilding an old organization without in any way impairing its essential strength. Dr. McLaughlin came to Massachusetts on leave from the United States Public Health Service. Unfortunately, the exigencies of World War I necessitated his recall to Washington before the term for which he was appointed was up. Nevertheless, before he left he had placed the Department of Health firmly on its feet and, to a large extent, had charted the course it has followed ever since.

The organization of the Department of Health, as has already been indicated, consisted of a full-time commissioner, "skilled in sanitary science and

experienced in public health administration," and a public-health council consisting of the commissioner *ex officio* and six members appointed by the governor. The executive and administrative functions were centered in the commissioner, whereas the council had for its functions the making and promulgation of rules and regulations, the taking of evidence in appeals, the holding of hearings and the consideration of plans and appointments required by law. Certain divisions were established, and a system of full-time district health officers was set up.

One of the faults of the old State Board of Health had been its excessive centralization. This was remedied in the new department by the establishment of six divisions, each with a director, who, with one temporary exception, was a full-time worker. These divisions included sanitary engineering, water and sewage laboratories, food and drugs, communicable diseases, biological laboratories and hygiene. In addition, eight health districts were created, with a full-time medical health officer in each. These men were placed in the Division of Communicable Diseases for administrative purposes, but were expected to represent the commissioner in their own districts. This feature of the Department was not entirely new, since a somewhat similar system had been in effect under the State Board of Health. Beginning in 1898 with one man, there were later fifteen inspectors of health, who, however, were required to give only part of their time to this work. Much of the time of these early inspectors of health was devoted to factory inspections. With the creation of the State Board of Labor and Industries, this responsibility was transferred to the new board.

Important as were the duties of the state district health officers, there was a lack of adequate assistance. As a rule there was no local office provided and no clerical assistance. Clerical work had to be done during intervals of visiting boards of health, investigating epidemics, getting materials for case records, looking up all cases of ophthalmia neonatorum and carrying on educational work in the various communities of the district.

COMMUNICABLE DISEASE THEN AND NOW

As an example of the tremendous problem that faced the Department in investigating communicable diseases, one may refer to an early statement of the new commissioner, allocating the annual deaths from preventable diseases in Massachusetts to the various divisions best prepared to aid in their prevention. The Division of Communicable Diseases, for example, in 1915 was charged with 15,920 deaths, which included those from syphilis, tuberculosis, pneumonia, diphtheria, measles, scarlet fever, typhoid fever, whooping cough and influenza. Later, owing to other arrangements for handling these diseases, syphilis and tuberculosis were removed from this list, leaving a total of 7920 deaths

within the province of the Division of Communicable Diseases. It goes without saying that a detailed investigation of each of these deaths would have been utterly impossible; only epidemics as a rule could be carefully inquired into. It is interesting to note that if the deaths from these same diseases had been reallocated at the beginning of 1944, the total number would have been 1020 instead of 7920. This great change in the number of annual deaths cannot, of course, be charged to the credit of the Department alone. It does, however, represent the results of the combined efforts of local and state departments of health in co-operation with the medical profession and a far better-informed public.

When the Department of Health was created, all its efforts toward reducing the incidence and death rate of tuberculosis and of the venereal diseases were centered in the Division of Communicable Diseases. Later, however, a Division of Tuberculosis was created, and much later still a Division of Venereal Diseases. In the case of tuberculosis, shortly after 1915 it was felt that better provision should be made for the hospitalization of open cases and the detection of early cases through local dispensary service. This sentiment resulted in legislation establishing county tuberculosis hospitals and extending local dispensary service. Regarding the problem of venereal diseases, which up to the time of World War I had never been adequately discussed, to say nothing of being adequately treated, a great deal of study was given to ways of remedying this condition. A plan was worked out for the reporting of venereal disease by physicians directly to the Department by means of numbers, identification by name being left as a last resort in careless or recalcitrant cases.

Another difficult problem attacked in these early years was that of milk sanitation. Milk at that time was a subject of heated controversy. Epidemics of septic sore throat were far from infrequent, yet the simple expedient of pasteurization of milk on the scale on which it is now practiced was merely a hope for the future. A valuable study of the whole question was made by a milk board made up of members of the Department, and served its purpose in bringing about a better understanding of the whole question.

PERSONAL AND COMMUNITY HYGIENE

The period between the establishment of the State Board of Health in 1869 and its reorganization in 1914 may rightly be called primarily the era of sanitary control of the environment. This was the period of the great progress in water and sewage purification already referred to. At the same time strides were made in the direction of adequate supervision of foods and drugs.

Beginning, however, in 1915, a determined effort was made under the leadership of Dr. McLaughlin to carry to the average citizen as much as possible

of the knowledge and practices already familiar to public-health workers, in order that the measures initiated by health officials might be better understood and receive more adequate support. Certain aspects of this educational work had to be taken to the medical profession as well, particularly in the case of ophthalmia neonatorum. At the beginning of this period, cases of ophthalmia neonatorum were extremely frequent and blindness often resulted. Years of investigation of each case of sore eyes in newborn babies and the instigation of proper treatment resulted in the almost complete disappearance of blindness due to ophthalmia neonatorum.

Infant mortality at that time judged by present-day standards was startlingly high. Approximately 10,000 infants under one year of age were lost every year in Massachusetts, as compared with about 2700 in recent years. The Department undertook to instruct parents in the simple procedures of infant hygiene and to get prospective mothers to their family physicians for prenatal care.

The need for this kind of instruction led to the first use of public-health nurses. Early in the life of the Department the Division of Hygiene employed two nurses as health instructors. Gradually the number of public-health nurses increased, and the scope of their work broadened until it became one of the most important phases of the Department's work. A beginning was also made in more highly specialized health instruction through the appointment of a health instructor in foods.

One of the most outstanding of all the special efforts directed against infant and maternal mortality was inaugurated when Dr. McLaughlin was able to bring about an alliance between the Department and certain outstanding private agencies whereby it was found possible to get together a group of eight public-health nurses whose salaries were paid by money received from the American Red Cross. Expenses were carried by the Department. A Child Conservation Committee was appointed by the commissioner, chosen from members of the Department and assisted by a large and distinguished advisory committee made up of outside specialists. Under the direction of this committee careful and detailed studies were made in each town in the Commonwealth, and after careful consideration by the Child Conservation Committee these were translated into definite recommendations to the proper authorities of these towns.

EUGENE R. KELLEY, THE SECOND COMMISSIONER

In 1918, to the great regret of the Department and all interested in it, Dr. McLaughlin was recalled to Washington for war duty and was succeeded as commissioner by Dr. Eugene R. Kelley, who had served with Dr. McLaughlin from the beginning as director of the Division of Communicable Diseases.

Dr. Kelley was at the time a relatively young and vigorous man who before coming to Massachusetts had served as health commissioner of the State of Washington. Imbued with the principles for which Dr. McLaughlin stood, he took up the work where the latter had left it, and carried it forward with the changes that increasing public-health knowledge and increasing public-health consciousness made desirable and possible.

The first great change came in 1919 when the Legislature decided to do away with the large number of boards and commissions that had hitherto functioned in a somewhat overlapping manner and to set up in their place a far smaller number of more responsible departments. In this reorganization the Department of Health fared extremely well. Its name was changed to that of the Department of Public Health, and it received as part of the new Division of Tuberculosis the state sanatoriums hitherto under the jurisdiction of a board called the Trustees of Hospitals for Consumptives. This division was later to have another institution placed under its care, namely, the new Cancer Hospital at Pondville.

In 1929, an outstanding attempt was made under the inspiration of Dr. Henry D. Chadwick, afterward commissioner of public health, to reach tuberculosis at its source through the early detection of the disease in children. With Dr. Kelley's backing a ten-year tuberculosis program was begun; it was usually referred to as the Chadwick Clinics and was named, of course, after the man who conceived the idea and carried it to completion.

One of the problems of a good administration has always been to get those who are interested in a given field to co-operate adequately. The great field of the health of the child has always been of interest to the people of the Commonwealth. School medical inspection began as early as 1894 in Boston, and later legislation required medical and nursing supervision of all Massachusetts school children. Two state departments in the very nature of things are deeply concerned with the health of the school child, namely, the Department of Public Health and the Department of Education. Yet for many years there was little effective co-operation between these two departments. Dr. McLaughlin was deeply concerned over this, and shortly after Dr. Kelley succeeded to the commissionership a close relation was established, whereby both departments united to stimulate local interest in the school health problem and to aid local authorities in strengthening and increasing the work already in operation. The possibilities of such co-operation are unlimited.

As time went on the need was felt for additional specialization. Increased knowledge of nutrition and of the need of doing something to cut down the incidence of the universal disease, dental caries, led to the appointment by the Department of workers who specialized in these fields and who could serve

as consultants to the more generalized staff workers as well as to local organizations. Consultants in public health nursing stimulated to a remarkable degree the establishment of new public-health nursing services in the local communities.

Early in the history of the Department of Health, it was felt that something should be done toward reducing the cancer death rate. Not much seemed possible at that time, but it was believed that it would be a step in the right direction if a free tumor diagnostic clinic were established. This was done in 1919 through the co-operation of the Harvard Cancer Commission. In 1925, the Legislature directed the Department of Public Health and the Department of Public Welfare to make a study of the cancer situation in Massachusetts and to recommend necessary measures for successfully attacking this problem. Dr. Kelley's death occurred before this study was completed, but under his successor, a report was made to the Legislature, and as a result money was appropriated for a hospital to be devoted to the treatment of cancer patients. This cancer program has grown until it now represents the larger part of the activities of a special division in the Department, which has carried on extensive statistical studies and a great deal of public education, seemingly with demonstrated success.

GEORGE H. BIGELOW, PUBLIC-HEALTH EVANGELIST

On the death of Dr. Kelley after eight years' service as head of the Department, his deputy, Dr. George H. Bigelow, was chosen commissioner. With a brilliant mind and an energetic temperament, Dr. Bigelow threw himself wholeheartedly into the problems confronting the Department, struggling against public inertia, sometimes with indignation and at other times with a kind of sardonic humor that included both the obstructionist and himself. The measures proposed by Bigelow were as a rule sound, and have been or will ultimately be accepted as good public-health practice. If all milk were pasteurized, unquestionably Massachusetts would be a safer place in which to live. Even now, as a result of the insistence of Bigelow and his successors and other like-minded persons in and out of the Department, about 80 per cent of the population of this state live in communities that require that the milk supply be pasteurized or certified. Over 90 per cent of the milk consumed in the Commonwealth is pasteurized. Many of the other advances made during Dr. Bigelow's commissionership are referred to elsewhere.

After eight years of active leadership, Dr. Bigelow left the Department to become director of the Massachusetts General Hospital and was succeeded by Dr. Henry D. Chadwick, who had been associated with the Department of Public Health for many years as superintendent of the Westfield Sanatorium, director of the Division of Tuberculosis

and guiding spirit in the promotion of the childhood tuberculosis program.

LATER MILESTONES

At this point we shall have to take leave of personalities, since all those who have been connected with the later activities of the Department are still alive. The development of the Department of Public Health has continued and parallels the general advances in public health throughout the country and the world.

One of the later developments of considerable interest was the study made in 1935 and 1936 by the Massachusetts State Health Commission. This commission was appointed by the governor and was made up both of members of the Department and of outstanding medical and public-health experts from outside the Department staff. The commission studied existing health laws and practices and made suggestions for legislation that would anticipate normal expansion for years to come. The Legislature accepted some of these suggestions, which have been translated into statutes.

The year 1934 saw the ending of the ten-year tuberculosis program. From that time on the work has been carried on in a more or less decentralized way through county and state sanatoriums. Actual or suspected cases of tuberculosis in children are followed up through examinations by a state clinic group. During the period of the demonstration program about 400,000 school children were examined, and the importance of the prevention of tuberculosis has been brought home to practically every family in the Commonwealth.

In 1935, a pneumonia study that had been begun in 1931 with the financial support of the Commonwealth Fund of New York City was concluded. At that time the Department assumed the expense of preparation and distribution of serum for the treatment of this disease. Three books on pneumonia were written as part of this study, one a handbook for physicians on the treatment of pneumonia.

Experimental work was carried on with reference to the preparation and evaluation of placental extract in the control of measles. This was financed by the Commonwealth Fund, and the work was done by the Harvard Medical School through the Children's Hospital and in co-operation with the Department of Public Health.

During this year also the cancer work was extended by the legislative provision for a cancer and tuberculosis unit to be built on the grounds of the Westfield State Sanatorium.

The year 1936 was noteworthy for the beginning of participation by the Department of Public Health in the activities provided for in the federal Social Security Act. It is difficult to estimate the potentialities for the future of this type of federal and state co-operation. It brought and continues to bring to the Department large sums of money, both

through federal grants and through state appropriations, and involves a great expansion of both personnel and activity. The latest example of this is the Emergency Maternal and Infant Care Program for the wives of certain men in the armed services of the United States. Other specific examples of the use of Social Security funds are the programs for the care of crippled children and the control of venereal disease. It is altogether too early to assess accurately the future possibilities or, for that matter, the drawbacks in this type of joint action.

In 1937, under the provisions of an act of the Legislature, the Department of Public Health obtained funds for the hospitalization of a limited number of cases of chronic rheumatism. This work has been carried on under a contract with the Massachusetts General Hospital.

In 1939, because of the appearance of equine encephalomyelitis, the Department carried out an extensive study of the mosquito situation in Massachusetts as an aid in reaching some determination as to the way in which this disease is spread. Definite conclusions will have to await further opportunities for study.

One of the newer efforts to raise the standards of public-health practices stemmed from the recommendations of the Massachusetts State Health Commission, already referred to, and had to do with the approval of bacteriologic and serologic laboratories by the Department of Public Health. Under the provisions of this statute such laboratories may apply to the Department for approval. This is purely voluntary on the part of laboratories, except in the case of those that wish to perform serologic tests for syphilis in cases of pregnancy and those wishing to qualify for performing premarital examinations. This work is going on quite satisfactorily and is meeting with a good response from the laboratories.

In 1941, legislation was passed under which hospitals are licensed by the Department of Public Health in accordance with regulations promulgated by the Department. Provision for licensing dispensaries had been made many years previously.

The Department of Public Health has now reached the point where, because of its size and its varied activities, considerably more decentralization is necessary. In view of the traditional policy of the Commonwealth to delegate in so far as possible authority in public-health matters to the local boards of health of the various municipalities, large and small, it is more or less imperative that these communities, especially the smaller ones, be able to obtain easily advice and assistance from the Department. From the earliest days of the State Board of Health, assistance of this sort has been offered, and as time has gone on, more and more facilities have been provided for this purpose. The establishment of the district-health-officer plan marked a great increase in efficiency on the part of the Department of Health. It has been found, however, that a

further step must be taken involving the strengthening of the district offices and the placing under them of all types of services that the Department has to offer to the local communities. This strengthening is progressing at a steady rate. By this and other means, it is confidently expected that the Department will be in a position to meet the many changes that the future will undoubtedly bring in the field of public-health administration.

SUMMARY

Seventy-five years ago, in 1869, Massachusetts established a state board of health. This was the first unit functioning from the beginning as a state board of health. It came about after twenty years of discussion following the presentation to the Legislature of a remarkable document on sanitation, largely written by Lemuel Shattuck.

The Board of Health functioned as such from 1869 to 1879 and then was merged in the State Board of Health, Lunacy and Charity. This combination lasted for seven years, but in 1886 it was seen to be desirable that the Board of Health be made independent once more.

From 1886 to 1914, the Board of Health became increasingly necessary as public-health knowledge increased; it not only played an honorable part but

added greatly to the knowledge of its time. In 1914, the board was transformed into the Department of Health, with responsibility centered in a commissioner of health. In 1919, the name was changed to the Department of Public Health, and as such it has continued to the present time.

An attempt has been made to show the progress of the public-health movement in Massachusetts by discussing the accomplishments of certain outstanding men, beginning with Henry Ingersoll Bowditch and following down through the years with Dr. Henry Pickering Walcott, Mr. Hiram F. Mills, Dr. Samuel Abbott, Dr. Allan J. McLaughlin, Dr. Eugene R. Kelley, Dr. George H. Bigelow and their successors.

A constant advance is evident, conservative but steady and paralleling the best being made in the rest of America and throughout the world. The Department is now at the height of its efficiency and opportunity for service to the people of the Commonwealth, and is looking forward to taking its part in the still greater public health that undoubtedly lies ahead.

ACUTE PHOSPHORUS POISONING*

Report of a Case with Recovery

T. E. CHRETIEN, M.D.†

SOMERVILLE, MASSACHUSETTS

AT ONE time phosphorus was a common poison owing to the use of yellow phosphorus in match tips. This practice is now prohibited by law, and as a result the number of deaths from phosphorus poisoning has been greatly reduced.¹ Phosphorus is, however, still used in various forms of rat and roach pastes that are easily available to the pica of some children in certain environments. Several deaths of children have been reported from eating fireworks, especially the so-called "spit devil" variety.² The majority of cases of phosphorus poisoning in adults are the result of suicidal attempts, some form of rat paste or vermin killer containing 1 to 4 per cent phosphorus being used. Cases have been reported in which phosphorus was used as an abortifacient.³

Toxic Dose

The toxicity depends to a great extent on the physical state of the phosphorus, which governs the rate of absorption, as well as on personal peculiarities, those who are the subject of nervous diseases

probably being somewhat more susceptible than others.² Death has occurred after the ingestion of match heads estimated to contain 65 to 130 mg., but recovery has occurred after the taking of about 400 mg. In one of Smith's³ cases, match heads made of yellow phosphorus were enclosed in sweets and used for homicidal purposes; although a sweet containing 200 mg. of phosphorus was taken, the patient recovered after severe symptoms.¹ The consensus is that a dose of 50 to 65 mg. will produce decidedly dangerous or fatal symptoms in a healthy adult.²

Symptoms and Signs

There are two phases in the symptomatology — a primary one due to local irritation of the gastrointestinal tract, and a secondary one due to the action of the absorbed poisons.

The primary symptoms are usually delayed for two to six hours following ingestion. They consist of abdominal pain, burning, nausea, vomiting and diarrhea. The breath and vomitus have a characteristic garlic odor, and the vomitus is frequently

*From the Medical Service of the Newton Hospital, Newton Lower Falls, Massachusetts.

†Formerly, intern, Newton Hospital.

luminous. Thirst is usually intense, and gaseous eructations are frequent. Diarrhea is a variable feature, occurring in about one third of the cases; when it is present the feces may be dark and luminous.

If the patient does not succumb to shock from the immediate effects of the phosphorus, there ensues a period of two or three days when the patient shows marked improvement, following which the second stage of poisoning is heralded by nausea and by protracted emesis, which produces a blood-streaked vomitus, diarrhea and abdominal tenderness in the region of the liver. The conjunctivas and the skin become jaundiced. There are headache, weakness and malaise. There may be bleeding from the nose or vagina, and hemorrhagic spots may appear under the skin and mucous membranes. The urine becomes scant and highly colored and contains blood, droplets of free fat and albumin; the urea content is lessened, and amino acids, especially leucin and tyrosin, are present.² Lawrence and Huffman⁴ call attention to an increase in the number of monocytes in the blood. Marked leukopenia has never been reported, so far as is known, but in the case here reported the white-cell count was 1200 on the day of admission. There is usually a definite decrease in the blood sugar, which is explained by failure of glycogenolysis, owing to liver destruction, to check the downward course of the sugar level.⁵ The liver is usually enlarged. There is frequently slight fever, the pulse becomes rapid, weak and irregular, and the patient gradually sinks, dying within about a week after ingestion of the poison.¹

Pathology

It is clear that the post-mortem changes vary with the duration of the poisoning. The skin is jaundiced, and hemorrhagic spots may be visible over the skin. On opening the body a garlic odor may be noted, and in acute cases the stomach contents have a faintly luminous appearance. The mucous membrane of the gastrointestinal tract shows inflammatory reaction and occasionally small erosions. Patches of submucous hemorrhage may be observed. Phosphorus is one of the most potent causes of fatty degeneration, and this change is present in marked degree in the liver, kidneys, heart and even the voluntary muscles.⁶ The nervous system is also vulnerable to phosphorus. The inferior olivary bodies and the lipophilic cells are involved early and account for the symptoms referable to the central nervous system.⁷

The liver shows the most characteristic changes; it is usually enlarged and of a lemon-yellow tint, it feels greasy and soft, and small hemorrhages may be seen on the surface and in the substance. Microscopically, extensive fatty degeneration of the liver cells is observed, the accumulation of fat in Kupffer's cells being an early manifestation.⁴ The kidneys are

larger than normal, icteric in color and of a very soft consistence. They also show marked fatty degeneration microscopically.

Phosphorus may be detected in its unoxidized form for several days, and it has been found in the body after burial for a month. Scherer's test is a good preliminary one, but since it is not specific and is affected by a variety of reducing agents, it is of value only in proving the absence of phosphorus or in indicating the desirability of other, more specific tests. The most reliable test is the Mitscherlich method, which depends on separation of free phosphorus in a current of steam, where it phosphoresces. Both these tests are described in Smith's *Forensic Medicine*.¹

CASE REPORT

D. C. (K-1889), a 23-year-old, Italian schoolteacher, entered the Newton Hospital on March 3, 1944, and was discharged on March 28. The diagnosis was acute phosphorus poisoning. The past history and family history were noncontributory. Four days prior to admission, following an argument with her fiancé, the patient ingested more than a teaspoonful of a rat and roach paste that contains 2.5 per cent phosphorus and 97.5 per cent inert matter. The amount of phosphorus ingested was estimated at about 130 mg. Because of fear the patient consulted a local physician an hour later, and he suggested that milk be taken immediately. Two glasses of milk were then ingested, followed half an hour later by a drink of whisky. Three hours after ingestion of the poison the patient began to have a headache, felt dizzy and nauseated and had epigastric pain. There were frequent attacks of vomiting during the night, the vomitus appearing "bright yellow and glowing." The vomiting relieved the abdominal pain for a short time. The mouth became extremely dry. The abdominal pain soon recurred and was severe enough to cause groaning. A severe headache developed and persisted up to admission. The following night the patient felt improved enough to attend a dance. Two days later she became so dizzy and weak that she was forced to remain in bed. Marked nausea returned, with occasional vomiting, and the abdominal pain also returned. The urine became highly colored and somewhat reduced in amount. A physician advised immediate hospitalization.

Physical examination revealed an alert young woman lying in bed in no apparent acute distress. There was a faint lemon-yellow color to the skin. The conjunctivas were icteric. The pupils were equal and reacted to light. There was a small, dried, bloody crust in the right nostril. The mucous membranes of the mouth were somewhat pale. No petechiae were present. The tongue was dry, with a gray coating. The neck was not rigid, and a few nontender cervical lymph nodes were palpated bilaterally. The lungs were resonant and clear. The heart sounds were good, with a regular rhythm and a rate of 90. A soft systolic murmur was heard over the precordium and was maximum at the apex. There was moderate tenderness to palpation in the right upper quadrant of the abdomen. The liver could not be palpated. No masses were felt, and the remainder of the examination was essentially negative. The temperature was 99°F., the pulse 80, and the respirations 15. The blood pressure was 110/70. The urine showed a specific gravity of 1.022, no albumin and complete reduction of Benedict's solution (the patient had just received 1000 cc. of 10 per cent glucose solution parenterally). The sediment contained 2 to 4 red cells per high-power field and no leucine or tyrocin. The red-cell count was 4,200,000 and the hemoglobin 86 per cent. The white-cell count was 1200, with 24 per cent segmented neutrophils, 8 per cent young neutrophils and 68 per cent lymphocytes.

The day following admission, the jaundice was more evident and the patient complained of a garlicklike taste in the mouth. She was still nauseated but was able to take fluids. There were two episodes of nosebleed from the left nostril. The nonprotein nitrogen was 47.7 mg. per 100 cc., the icteric index 37, and the bilirubin 9 mg. (direct). The prothrombin

time was 28 seconds (normal, 18 seconds). The urine revealed a slight trace of albumin, with 60 to 100 red cells per high-power field. A hile test was positive, and urobilinogen was positive in a 1:30 dilution. For the following 2 days the patient felt generally improved, with no complaints except tightness in the chest, tingling in the veins and slight dizziness following Pentnucleotide therapy for the leukopenia. The jaundice, however, had definitely increased. The liver was felt 2 fingerbreadths below the right costal margin.

Five days after admission, the icteric index had risen to 111, and the white-cell count to 5000. The urine was still negative for tyrosine and leucine crystals. An electrocardiogram revealed a sinoauricular tachycardia, with an occasional extrasystole. There was no evidence of myocardial damage. The following day the jaundice began to clear, and from then on the patient made an uneventful recovery. On the 18th day, the jaundice had cleared except for a slight icteric tinge to the conjunctivas. The prothrombin time was 20 seconds. A bromsulfalein test was normal. The serum bilirubin was 2 mg. per 100 cc., and the icteric index 18. The white-cell count was 9400 and the red-cell count 4,200,000 with a hemoglobin of 84 per cent. The patient was discharged improved on March 24 with instructions to return to the Outpatient Department for a follow-up.

Treatment consisted of a high-carbohydrate, low-fat diet, with daily intravenous infusions of 10 per cent glucose in saline solution. Twenty units of regular insulin was administered intramuscularly prior to the intravenous infusions. One gram of calcium gluconate was administered orally three times daily. One hundred milligrams of thiamine hydrochloride and 200 mg. of ascorbic acid were administered intramuscularly daily. For the marked leukopenia 10 cc. of Pentnucleotide was given intramuscularly three times a day for 3 days, twice a day for 4 days, once daily for 4 days, and then once every other day until the white-cell count reached 9000. The urine was maintained at pH 7.5 with sodium bicarbonate by mouth.

In addition to the treatment in this case, when patients are seen early every attempt should be made to prevent the absorption of orally ingested phosphorus. Gastric lavage should be performed even if the patient is first seen several hours after the poison has been taken. A suitable chemical antidote is copper sulfate (0.25 gm. in a glass of water), the effect of which is to envelop the phosphorus particles with an insoluble coating of copper phosphide. Oxidizing agents, such as potassium permanganate (1:1000 solution) and hydrogen peroxide (2 per cent of the official preparation), may aid the conversion of elemental phosphorus to harmless oxidation products. Following gastric lavage,

a cathartic of magnesium sulfate should be administered to cleanse the bowels.⁸

* * *

Phosphorus is a severe destructive poison. It is rapidly absorbed through the gastrointestinal tract and manifests itself by fatty degeneration and infiltration of the brain, liver, kidneys and practically all the other viscera of the body. The early symptoms are usually those of insult to the central nervous system and those due to local irritant action, as in the gastrointestinal tract. Later the symptoms are those of liver destruction, with jaundice, enlargement of the liver, an increased icteric index and usually hypoglycemia. Most cases of phosphorus poisoning have terminated fatally; hence, it is essential to make a diagnosis as soon as possible and institute treatment immediately. These cases should always be considered as emergencies.⁹

SUMMARY

Acute phosphorus poisoning is described from the standpoint of toxicity, symptomatology and pathology.

A case of acute phosphorus poisoning due to ingestion of a rat paste, with an uneventful recovery, is reported.

MEDICAL PROGRESS

HEMATOLOGY

WILLIAM DAMESHEK, M.D.*

BOSTON

ALTHOUGH anemia is by no means all of hematology, it is often considered its most important phase. This year's review will be limited to a more or less personalized discussion of this subject.

GENERAL CONSIDERATIONS

Classification

The terms "secondary anemia" and "primary anemia" must by now be considered as clearly outmoded. Since anemia is always a symptom of some underlying disorder, all anemias are necessarily secondary. If this is the case, there is no point in discriminating between primary and secondary cases. The classification of anemia on the basis of color index, cell volume or cell diameter, or all three, has become deservedly popular, chiefly because it gives orientation regarding the possible etiologic and therapeutic factors in a given case. Thus hypochromic microcytic anemia is usually indicative of chronic iron deficiency and of a probable therapeutic response to iron rather than to liver. These features are listed in Table 1.

For a complete classification, cell size and color index are, however, not enough; the important con-

sideration is the factor of storage is affected; and multiple pregnancies, in which the developing fetus absorbs an exceptional amount of material from the mother. Single etiologic factors are by no means as important in this regard, however, as multiple causes. Thus a woman on an inadequate intake of iron does not usually develop anemia unless she also has a gastric disturbance (achlorhydria) and either many pregnancies or menorrhagia. And an individual with sprue probably not only has a deficient diet but a chronic intestinal disturbance as well.

Anemia due to a bone-marrow disturbance is normochromic and normocytic because, although red-cell production is more or less seriously impaired, the red cells that are produced are of normal size and hemoglobin content. There is likewise an associated leukopenia and thrombocytopenia, — that is, pancytopenia, — since if the bone-marrow is the site of involvement, *all* its elements are usually affected. Numerous disturbances of the bone-marrow itself are known: aplasia and hypoplasia, as with benzol and other types of chemical poisoning and the hypoplasia of myxedema and of chronic nephritis with azotemia; replacement by leukemia,

TABLE 1. *Classification of Anemias According to Cell Size, Color Index and So Forth.*

TYPE OF ANEMIA	COLOR INDEX	CELL DIAMETER (M. C. D.) microns	CELL VOLUME (M. C. V.) cu. microns	PROBABLE CAUSE	PROBABLE EFFECTIVE THERAPY
Normocytic	0.9-1.1	7.3-7.8	85-100	Bone-marrow disturbance	Transfusions (?)
Microcytic	0.4-0.8	5.5-6.5	65-85	Iron deficiency	Iron
Macrocytic	Above 1.1	7.8-8.3	100-130	Liver-extract deficiency	Liver extract

sideration is the *cause* of the anemia. In every case, it is essential, preferably before therapy is begun, to attempt a definition of etiologic factors. This can generally be done if it is remembered that anemia is usually due to one of three factors: a deficiency of materials requisite for blood formation; a disturbance in the marrow; and an increased loss of the bone-marrow's finished product, the red cell, either through hemorrhage or increased hemolysis.

The deficiency anemias are caused by a variety of factors: a dietary that is deficient in iron, protein or vitamin B complex; an inadequacy of the gastric juice, which is deficient in either free hydrochloric acid or Castle's enzyme ("intrinsic factor"); chronic intestinal malabsorption, as in chronic diarrhea, sprue and so forth; hepatic disease, in

lymphosarcoma, multiple myeloma and other tumors; and diminished or inhibited delivery, as in hypersplenism (see below). The bone-marrow biopsy, whether by puncture or trephine, is of the utmost value in the differential diagnosis of these conditions.

Anemia due to excessive blood loss may be either hemorrhagic or hemolytic in type. Severe hypochromic anemia due to chronic slight bleeding from the gastrointestinal tract often remains undiagnosed, and is frequently mistreated, usually by means of continued injections of liver extract. The blood picture of chronic hypochromic microcytic anemia in association with increased polychromatophilia of the red cells, a slight increase in the reticulocytes, polychromatophilic target cells, increased platelets and a slight "shift to the left" of the polymorphonuclear cells is usually due to chronic bleeding and

*Professor of clinical medicine, Tufts College Medical School; visiting physician and hematologist, New England Medical Center.

not to simple iron deficiency. Anemia due to excessive hemolysis is usually associated with a normal or increased color index, and a normal or increased cell volume in the presence of small red cells, that is, the cells are thicker than normal. Bilirubinemia is present, and the reticulocytes are greatly increased.

From the foregoing, it may be seen that, in any given case of anemia, it is necessary to determine among other things, the factors of color index, cell volume and cell size and the various etiologic factors concerned. The classification that I prefer at present is based on both these criteria. Thus a given case may be classified as follows: macrocytic anemia, inadequate intake of protein, gastric achlorhydria — that is, liver-extract deficiency or pernicious anemia: microcytic, hypochromic anemia, inadequate intake of iron, gastric achlorhydria, profuse menses — that is, chronic hypochromic, iron-deficiency anemia; or normochromic, normocytic anemia, benzol poisoning — that is, aplastic anemia.

Diagnosis

The working out of the etiologic factors in a given case presenting anemia as one of its features may either be simple or quite complex. As in other branches of medicine, one has recourse to every available bit of data derived from the history, the physical examination and the various laboratory tests, including x-ray examination and the sternal bone-marrow biopsy.

From the history one learns about the diet, the matter of gastrointestinal symptoms, the question of bleeding into the skin or from various organs and such miscellaneous symptoms as glossitis, weight loss, pains in bones and fever. The family history is important from the standpoints of anemia, early graying of the hair, jaundice and so forth. When taken with proper regard to possible disease entities, a careful history often suggests the diagnosis.

In the physical examination one pays particular heed to the questions of pallor, icterus, the appearance of the tongue, the matter of enlarged peripheral lymph nodes and the size of the spleen and liver. Careful inspection of the skin and buccal mucous membranes should be made for petechiae, ecchymoses and spider telangiectasia. The remainder of the physical examination is by no means neglected because many so-called "blood cases" turn out to have a general disease, such as myxedema, nephritis or subacute bacterial endocarditis.

The laboratory data required for diagnosis may be extensive, but often a few simple tests of the blood give the probable diagnosis. The hemoglobin estimation should be done either with a well-calibrated hemometer or preferably by means of a photoelectric colorimeter. Red-cell, white-cell and differential counts are ordinarily sufficient, although in many cases it is important to know, or at least to estimate, the platelet and reticulocyte levels. Estimations of these factors are made by noting

the extent of polychromatophilia and the abundance of the platelets in the stained smear. The hematocrit is valuable from the standpoint of determination of the mean corpuscular volume and thus of the red-cell size. Bilirubin determinations are important from the standpoint of hemolysis. Many other tests are occasionally brought into play. These include determination of the hypotonic and other fragilities, the question of hemolysins and agglutinins, examination of the stools for occult blood and urobilinogen, liver-function studies and gastric analysis.

In the cases with pancytopenia, no test is of greater importance than a biopsy of the sternal marrow. In most cases, a simple needle aspiration is sufficient to make a positive diagnosis (leukemia, multiple myeloma, hemolytic anemia and so forth). Occasionally, however, removal of a button of bone by the trephine method becomes necessary, particularly when needle aspiration is unsuccessful. This is particularly the case when fibrosis, aplasia or metastatic malignancy is present. By this method the topography of the marrow and the relation of cellular elements to bone, fibrous tissue and so forth can be recognized at a glance. Metastatic nodules, clumps of Gaucher cells and diffuse myelofibrosis are readily recognized. In my own work-up of a hematologic problem, a sternal puncture aspiration is performed as a routine measure; it not only gives diagnostic help but also is of assistance regarding the pathologic physiology of various disease conditions.

DEFICIENCY ANEMIAS

Chronic Iron Deficiency

A continued deficiency in iron results in a shortage of hemoglobin for the developing erythrocytes in the bone marrow. As a result, the normoblasts have inadequate cytoplasm and the mature non-nucleated red cells are small and hypochromic. The anemia, which is hypochromic and microcytic, is by no means the only evidence of iron deficiency, which becomes manifest as well by changes in certain epithelial structures. Thus, the skin becomes wrinkled and flabby, the hair dry and gray, the tongue red, atrophied and shiny, and the fingernails flattened. Indeed, changes of other epithelial structures, including atrophy of the esophageal mucosa with web formation and of the stomach and intestines, often occur.

A state of chronic iron deficiency is brought about in various ways — through a diet inadequate in iron-containing food, by way of gastric achlorhydria, chronic diarrhea, chronic hemorrhage or multiple pregnancies or by a combination of two or more of these factors. Fewer cases of this condition seem to turn up nowadays than formerly, perhaps because incomes are higher and dietary inadequacy is therefore lessened. One should never mistake a chronic "idiopathic" iron-deficiency state for a

reduction in hemoglobin due to chronic bleeding from the gastrointestinal tract; for this reason, studies of the stools for occult blood and careful x-ray examination of the gastrointestinal tract are important.

Chronic hypochromic anemia is far more frequent in women than in men, probably because of the drain of the monthly loss of appreciable quantities of blood with the menstrual cycle, and the loss of hemoglobin-building substances to the fetus in pregnancy. Bethell, Blecha and Van Sant¹ studied the dietary habits and hematologic values of a group of 484 pregnant women in two rural counties of Michigan. Although all the women were from farms and could thus presumably obtain adequate amounts of good food, only a small number met the present-day recommended allowances for pregnancy. The incidence of anemia, almost all of which was of the hypochromic iron-deficient type, was 25.4 per cent. There was a direct relation of the incidence of anemia to the degree of iron inadequacy. As the authors state:

Although, in adults, a low food intake of iron is not generally an important cause of anemia, an exception must be made in the case of pregnant women with their increased requirements. Moreover, pre-existing stores of iron are essential to meet these added needs. Therefore, it is the quantity of iron consumed before conception that largely determines later evidences of its deficiency.

Hypochromic anemia in young and adolescent women, and for which no cause is apparent, has for centuries been known as "chlorosis." Recently, the presence of complete achlorhydria in a gastric juice of low volume has been recognized as an important feature of the disorder. The lack of hydrochloric acid may result in an insufficient digestion of iron-containing food and thus in hypochromic anemia. Chlorosis has become a rarity, and male chlorosis is almost a curiosity. I have seen only one such case, that of an adolescent boy who had a hemoglobin value of less than 20 per cent and complete achlorhydria; there was rapid improvement with inorganic iron by mouth. Thomson,² however, found 9 cases of apparently idiopathic hypochromic anemia in adolescent male recruits. Pallor, a smooth tongue (4 cases), complete achlorhydria (5 cases, with hypochlorhydria in 4), apical systolic murmurs, a barely palpable spleen (4 cases), spooned nails (4 cases) and prompt response to inorganic iron were present.

The nutritional hypochromic anemias of early infancy are rather common, particularly when infants are kept too long on a low iron intake. Kracke and Platt³ point out that they may be due to such factors as prematurity and disorders of the alimentary tract, including celiac disease, diarrheas and intestinal parasites.

It should be remembered that hypochromia — a low color index — indicates a hemoglobin deficiency in the presence of more or less normally productive islands of red cells. Liver extract, for all its potency

in pernicious anemia, has no effect whatever, even of an additive type, in cases of iron deficiency. Its use in such cases has little justification. Curiously enough, many cases of chronic iron deficiency are treated for months with such wholly useless medications as liver extract, vitamin pills and so forth, while treatment with iron is withheld. The place of copper in the treatment of iron deficiency in man remains extremely questionable, although the group at the University of Wisconsin has consistently maintained the value of copper in both rat and human hemoglobin synthesis. In a recent paper, Maass, Michaud, Spector, Elvehjem and Hart⁴ present evidence that copper is similarly useful in the hemorrhagic anemia of puppies. The value of copper in the hemoglobin synthesis of milk-fed rats has recently been questioned by Smith and Medlicott,⁵ who found that it might stimulate erythropoiesis but did not cause an increase in hemoglobin.

Chronic Liver-Extract Deficiency (Pernicious Anemia)

In this condition, a deficiency in the liver-extract principle is brought about either by a grossly deficient protein content of the diet, by a lack of production of Castle's proteolytic enzyme ("intrinsic factor") by the stomach, by a loss of the liver-extract principle from the body because of malabsorption by the intestines, as in prolonged diarrhea, or by a failure of the liver to store or perhaps to make utilizable the liver-extract principle. Although lack of the proteolytic enzyme is probably by far the most significant factor in the etiology of the disease, it is quite likely in many cases that the disease does not fully develop until some other factor, such as dietary inadequacy or pregnancy, supervenes. The ensuing deficiency in liver-extract principle not only results in a malfunctioning, megaloblastic bone marrow and macrocytic anemia but also in disorders of epithelial structures and the central nervous system. Thus, the hair becomes gray or white early in life, the tongue loses its papillae, and the spinal cord may develop subacute combined degeneration. In fact, many cases with little anemia may show a high degree of neurologic involvement. In pernicious anemia one may discriminate four more or less distinct forms: a purely hematologic type, characterized by severe macrocytic anemia and by little if any neurologic involvement; a fundamentally neurologic type, characterized by combined system disease and by little if any anemia; a refractory type, in which therapy even with huge doses of liver extract is only partially effective (in this type free hydrochloric acid may be present to some extent in the gastric juice — the "achrestic anemia" of Israëls and Wilkinson⁶); and a hemolytic type, in which there is unusually striking jaundice and a large spleen.

That pernicious anemia is a deficiency state cannot seriously be questioned. That it is also, at least to some extent, a hemolytic anemia, is attested by

the acholuric icterus and the high pigment output in the feces and urine. The cause of the hemolytic component remains obscure. Johnson, Freeman and Longini⁷ present evidence that the red cells of untreated cases of pernicious anemia are unusually sensitive to the digestive products of fat and speculate that this may be one of the etiologic factors of the anemia. Many authorities believe that the piling up in the bone marrow of large numbers of primitive red cells and their forerunners results in their gradual destruction and thus in the formation of bilirubin. To my mind, this seems a more logical explanation of and one more compatible with the idea that the disease is a pure deficiency state with resultant changes in the bone marrow, epithelial structures and nervous system.

The constitutional nature of the disease is attested by its relatively high incidence in members of the same family (4 to 15 per cent in various statistics), and by its greatest incidence in blue-eyed, fair-haired people and its lowest incidence in brown-eyed, dark-haired people. In Negroes, the disease has been said to be rare. Schwartz and Gore⁸ found that this rarity was more apparent than real, at least at the Cook County Hospital in Chicago. There, of 1000 consecutive patients with pernicious anemia entering the hospital from 1931 to 1942, a total of 93 were Negroes. The incidence of the disease in Caucasians admitted to the hospital was 170 per 100,000, contrasting with the rate of 36 in Negroes. It was found that the Negroes tended to show a higher incidence in youth and a lower incidence in old age than did the Whites.

The pernicious anemia of pregnancy is infrequent, but when it occurs, it is liable to be extremely severe and rather markedly refractory to liver-extract therapy. It has a number of atypical features — lack of outspoken jaundice, lack of outspoken macrocytosis, presence of free hydrochloric acid in the gastric juice, no neurologic phenomena and slow response to liver extract.⁹ In a recent case, the patient walked into my office with a hemoglobin concentration of 14 per cent (2.2 gm.) and a red-cell count of 800,100. The bilirubin value was only 0.5 mg. per 100 cc., and the red-cell picture was by no means characteristic. The striking thing in the blood picture was the presence of numerous multilobulated polymorphonuclear cells (so-called "pernicious-anemia neutrophils"), and this was by far the best single clue to the diagnosis, which was substantiated by puncture of the sternal marrow. Response to massive therapy with liver extract was slow and was considerably aided by the use of several transfusions. The various clinical and laboratory features of this condition have been fully presented in a recent study by Callender.¹⁰ This author points out that the theory of a temporary intrinsic-factor deficiency during pregnancy does not fit in with all the facts related to the anemia, especially since liver extract is frequently ineffective. She also emphasizes

the atypicalness of the blood picture and the great value of the sternal puncture in diagnosis.

Carter and Traut¹¹ emphasize the cardiovascular manifestations, which they state occurred in 257 of 300 cases of pernicious anemia. This figure, however, is considerably invalidated by the inclusion of "weakness" as a cardiovascular symptom and its occurrence in 231, or 77 per cent, of the cases. The authors' conclusion that all the usual criteria of cardiovascular disease may occur solely as the result of anemia is, however, distinctly valid, together with the statement that these manifestations disappear after treatment with liver extract.

The symptoms of cord involvement in pernicious anemia are well known, but those relating to the brain are often unrecognized. The patient is frequently suspicious and even paranoid. I have seen a number who became psychotic as they grew older. Some of the most profound examples of neurasthenic disability are seen in this group of cases. Adams and Kubik¹² studied the histology of the central nervous system in 2 cases of pernicious anemia and found that the cerebral and spinal-cord lesions were almost identical, consisting of a more or less diffuse though uneven degeneration of the white matter. Attempts have been made to explain the neural symptoms of the disease as due to a deficiency differing from that which causes the anemia. At least in human beings, no such differentiation has been demonstrated. In swine, Wintrobe and his co-workers¹³ produced neurologic disease closely simulating that seen in human pernicious anemia by a diet deficient in pantothenic acid and pyridoxin. Macrocytic hyperchromic anemia did not, however, result.

The treatment of pernicious anemia consists in the continued and persistent use of liver extract, preferably by the injection of a highly concentrated preparation (10 to 15 units per cubic centimeter) given at frequent intervals. The interval varies from patient to patient, particularly according to the degree of neurologic involvement. With well-defined disease of the cord, overtreatment is preferable. Most patients require an injection at least once every two weeks, although some go for a month and others require weekly injections. Relapses occur in those who neglect systematic treatment. The length of time for the development of relapse is a highly individual matter that has been studied by Schwartz and Legere.¹⁴ They suggest that the amount of intrinsic factor secreted by the stomach, the adequacy of the diet, the storage capacity of the liver and certain obscure factors probably influence the duration of the remissions.

A significant problem that seems to be on the increase is the development of hypersensitivity to the injectable liver extract. In some cases, the patient goes into an alarming anaphylactic state, with generalized angioneurotic edema, bronchial asthma, vomiting and diarrhea, drop in blood pressure and

so forth. Schwartz¹⁵ states that allergic reactions occur in about 10 per cent of all patients so treated. In most cases, this is probably due to pork sensitization, since most liver extracts are derived from porcine livers. All that is usually required is to shift to a beef liver extract, such as the 15-unit (1 cc.) Lederle extract or the approximately 1 unit (1 cc.) Campolon (Winthrop) liver extract. Some patients become sensitized to all types of injectable liver, and in these, recourse must be had either to attempted desensitization, which is usually unsatisfactory, or to oral liver extract, oral liver or oral gastric extract (Ventriculin).

Another problem, at least for the pharmaceutical houses, is the matter of assaying liver-extract preparations. This requires the use of relapsed cases of pernicious anemia and the rigid control of such factors as the diet, previous administration of liver or liver extract, daily reticulocyte counts and the use of suboptimal doses of extract. Practically, few relapsed cases suitable for assay are seen, most of the patients having been rendered unsuitable by a previous injection of liver extract or a little liver taken a few days previously. Biologic and animal methods would, of course, be eminently desirable, but thus far no such method has proved of value. Using explants of bone marrow from normal guinea pigs, and measuring the degree of migration of cells in response to control solutions and those containing liver extract, Young and Bett¹⁶ found no consistent results. They were forced to conclude that no difference sufficiently marked to be used as the basis of an assay method existed between the responses to active and inactive extracts.

The greatest problem in therapy is not, however, the use of adequate amounts of properly assayed liver extract in properly diagnosed cases of pernicious anemia, but rather the continued use of liver extract injections in patients who have absolutely no need for this material. In the last year alone, I have personally seen about 20 patients, all of them women, with what I call "Tallqvist anemia" and who have been given continued and persistent injections of liver extract for periods varying from one to twelve years. At some time or other, the patient, her family or a new doctor becomes suspicious about the need for these injections and inquires whether they should be continued. The history is usually that of emotional instability, with numerous spells of feeling "low," "without pep" and so forth. The diagnosis of anemia has been made either by the Tallqvist scale or even more simply by inspection, and the patient is then started on her career of injections. An injection is quickly followed by an improvement in general well-being, but if one or two injections are missed, the patient again feels "low" and the blood is said to "drop." Physical examination in these cases is negative; particular attention should be paid to the tongue and the vibratory sensation, both of which are

usually normal. The blood counts are normal, as they might be in a well-treated case of pernicious anemia; the sternal marrow is normal. Gastric analysis is of utmost significance from the standpoint of differential diagnosis; if it shows free hydrochloric acid, as it almost always does, the diagnosis of pernicious anemia may be discarded, together with the necessity for continued injections of liver extract. A curious commentary on this matter is that practically every patient with anemia whom I have seen in the past few years has had numerous injections of liver extract *except those who have had pernicious anemia*. These patients have usually been referred to the hospital because of the possibility of carcinoma or some other serious disease.

Sprue

Both tropical and nontropical sprue are probably to a great extent intestinal disorders characterized by prolonged diarrhea, bulky foul-smelling stools and the development of numerous deficiencies. These probably occur because malabsorption from the bowel results in the deficient absorption of iron, liver-extract principle, vitamin B complex, the fat-soluble vitamins, including vitamin K, and calcium. The disorder is thus fundamentally different from that due to a purely gastric disturbance, such as that seen in pernicious anemia. In sprue, although glossitis and macrocytic anemia may be encountered as in pernicious anemia, there is no evidence of a hemolytic component, the central nervous system is rarely affected, the pigment output in the stool is low, and the slow response to liver extract differs greatly from the quick effect seen in pernicious anemia. Other evidences of intestinal malabsorption include an increased sugar tolerance, a diminished calcium level in the blood, at times associated with tetany, and hypoprothrombinemia. Careful examination of the small intestine by serial roentgenograms and by the "snap-shot" technic revealed changes in 8 successive cases of nontropical sprue characterized by "puddling" and the "moulage sign," together with other indications of a greatly disturbed small-bowel function.¹⁷ Whether these changes are simply secondary to vitamin B-complex deficiency or, as seems more likely, to an intestinal disorder due to multiple factors is not entirely clear at present. Whatever the mechanism, these patients are difficult to treat, often being refractory to liver extract, iron, vitamins and so forth. A crude extract of liver is preferable in view of the multiple deficiencies present. Celiac disease of children is probably a closely related condition.

CASE 31091

PRESENTATION OF CASE

A thirty-one-year-old lumber contractor was admitted to the hospital because of intermittent hematuria.

About six years prior to admission, without any preceding injury, the patient began to pass grossly bloody urine for periods of two days to two weeks at a time. The periods recurred at intervals, varying from about a week to several months and always cleared up spontaneously. They were usually precipitated by lifting heavy objects. There was no associated pain or tenderness, nor were there any other urinary symptoms.

Two months prior to admission the patient fell, striking the left flank with his elbow. One hour later he again developed hematuria, followed very shortly by severe pain in the left flank. He was admitted to a local hospital, where the hematuria and pain disappeared after several days of bed rest.

X-ray examination of the kidneys at that time revealed extensive calcification, presumably in the pyramids. He was referred to this hospital for study.

For about a year prior to admission the patient had noted blurring of vision, especially when reading. He had also complained of aching in the back and legs for about the same period of time. For seven or eight months preceding entry he had suffered with severe headaches, coming on at any time of the day and usually relieved by aspirin. There was no history of dizziness or tinnitus.

Ten years before entry the patient had had otitis media with mastoiditis, followed by a mastoidectomy.

*On leave of absence.

tomy. About two years prior to entry he had an attack of uncomplicated "scarlet fever," but continued to work throughout his illness.

Physical examination was essentially negative. The temperature was 98.6°F., the pulse 62, and the respirations 20. The blood pressure was 145 systolic, 85 diastolic.

Examination of the blood revealed a red-cell count of 4,830,000, with 15.4 gm. of hemoglobin, and a white-cell count of 7600, with 61 per cent neutrophils. Repeated urine examinations revealed a specific gravity ranging from 1.004 to 1.010, with + to +++ tests for albumin. The Sulkowitch test for urinary calcium phosphate was + to ++. The sediment (catheterized specimen) contained innumerable white cells and an occasional red cell and granular cast. Urine cultures showed moderate numbers of colon bacilli and nonhemolytic streptococci on a few occasions and no growth on others. The serum nonprotein nitrogen was 20 mg. per 100 cc., the protein 5.7 gm., the chloride 98 milliequiv. per liter and the carbon dioxide combining power 28.2 millimols. Several blood calcium determinations ranged from 11.1 to 11.6 mg. per 100 cc.; the phosphorus was 2.7 to 3.0 mg., and the phosphatase 5.5 Bodansky units. A phenolsulfalein test revealed 90 per cent dye excretion in one hour. The blood Hinton test was negative.

An intravenous pyelogram revealed multiple fine dense irregular areas of calcification having the general arrangement of staghorn calculi in both kidneys, more marked on the right. There were no areas of calcification in the ureters or bladder. The intravenous dye was excreted promptly. The pelvis were of normal size. The calyces on the right were obscured by calcification, but those on the left did not appear dilated. The upper end of the left ureter was moderately dilated. The bones were of normal density, and no cysts were seen.

A retrograde pyelogram on the fourth hospital day revealed that the areas of calcification described were within the kidney pyramids and bulged into the calyces, especially into the upper calyces on the left and the lower ones on the right. The cupping of the minor calyces was markedly increased, but there was no appreciable dilatation. The ureters were dilated down to the bladder and were moderately tortuous.

On the eleventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD C. REIFENSTEIN, JR.: This discussion can be divided into two parts — the nature of the lesions in the urinary tract, and the cause of these lesions.

The pathology in the urinary tract first indicated its presence by intermittent gross hematuria. The most frequent causes of grossly bloody urine are tumors, calculi and tuberculous infection of the urinary tract. The onset of hematuria with exertion favors a tumor or a calculus; the persistence of intermittent bleeding for over five years without other symptoms is rather against a tumor or tuberculous infection. The recent episode of pain in the left flank following trauma and the aching in the back and legs for about one year are consistent with calculi; the findings on x-ray examination of the urinary tract confirm the diagnosis. The appearance on the x-ray plates is that of small deposits of calcium in the tubules of the pyramids of both kidneys of the type called "nephrocalcinosis." I do not believe that this type of calcification has been observed in tuberculous disease of the kidney, and hence I shall not give further consideration to an acid-fast infection in the kidney. We shall assume that the hematuria is due to the nephrocalcinosis.

No areas of calcification were demonstrated in the ureters or bladder, and the pelves were of normal size. Both ureters were dilated and tortuous, findings that are rather hard to explain. There was no history of ureteral obstruction during the passage of stones, although it is conceivable that one may have been passed during the episode of left flank pain. This would not explain dilatation of the right ureter. It is also possible that congenital strictures may have been present. Dilatation of the ureters, however, does occur for reasons that are not entirely clear in connection with renal infection, and presumably this is the explanation in the case under discussion. Furthermore, the passage of blood clots would aggravate the dilatation.

It is clear that this patient had pyelonephritis: the fixation of the specific gravity of the urine, the albuminuria and the finding of innumerable white cells, of occasional red cells and granular casts and of colon bacilli and nonhemolytic streptococci are evidence of this. The satisfactory excretion of phenolsulfonephthalein dye and of the intravenous dye for the pyelogram and the relatively normal serum nonprotein nitrogen level indicate the lack of glomerular involvement. As a matter of fact, the serum nonprotein nitrogen of 20 mg. per 100 cc. is slightly above the average normal value of 15 mg., and is consistent with the chloride level of 98 milliequiv. per liter, which is on the low side of average normal (103 milliequiv.), and with the carbon dioxide combining power of 28.2 millimols,

which is slightly on the high side of average normal (25 millimols). These slight changes are probably indicative of a mild state of dehydration. They are of no importance except to indicate that the low serum protein level (5.7 gm.) is even more significant than is apparent from the comparison with the normal levels of 6.5 to 8 gm. The hypoproteinemia was presumably due to the proteinuria.

Before I discuss the cause of these lesions, I shall consider for a moment the chemical nature of the calcification in the kidneys. Nephrocalcinosis of the type present in this patient is usually due to deposition of calcium phosphate concretions in the tubules. It is probable that the calcification increased after the pyelonephritis was established. This additional growth of the calculi would also tend to be deposition of calcium, since calcium tends to be thrown out in an alkaline urine, and colon bacilli and nonhemolytic streptococci are known to split urea and form an alkaline urine.

The second part of the discussion has to do with the cause of the nephrocalcinosis and of the pyelonephritis. The first question to decide is whether the pyelonephritis preceded or followed the nephrocalcinosis. Both situations are possible. There is little evidence, however, that the pyelonephritis preceded the calculi in this patient. We have assumed that the hematuria was due to the calculi. There was no history of renal disease prior to the hematuria. Although the patient did have otitis media and mastoiditis four years before the onset of hematuria, no renal complications are noted as sequelae to these infections. It is perhaps significant, therefore, that four years after the onset of hematuria the patient had an attack of what is called "uncomplicated scarlet fever," throughout which he worked. This may have been the infection that led to the pyelonephritis, which could readily have been established in kidneys already damaged with calcification. The case report makes no reference to the status of the teeth. Examination of the x-ray films of the jaws reveals at least two apical abscesses. Since spread of infection from an apical abscess to the kidney is quite frequent, the pyelonephritis may have had its origin from the infection around the teeth. We have no way of knowing how long these abscesses had been present. It is of interest, however, that only a year after the attack of scarlet fever the patient began to have blurring vision and severe headaches, both of which could be manifestations of renal infection. These symptoms were present only about one year before admission. Some significance might be given to the systolic blood-pressure level, which was perhaps a little higher than one would expect unless the patient was beginning to develop hypertension. The finding is consistent with a pyelonephritis of rather short duration. Further evidence that the nephrocalcinosis was present before the renal infection is derived from the fact that when pyelonephritis causes cal-

culus formation in the kidney it produces an entirely different type of calcification, which is in the renal pelvis rather than in the pyramids themselves.

If we assume that the nephrocalcinosis preceded the pyelonephritis, we then have to determine why the patient developed the nephrocalcinosis. Calcium deposits in the kidney occur from a supersaturation of calcium in the urine. In the absence of infection, in general, there are four causes for such a supersaturation: ingestion of too much calcium, leading to hypercalciuria; ingestion of too much alkali, leading to an alkaline urine, which favors calcium deposition; a blood acidosis, leading to resorption from bone of excessive amounts of calcium and to excretion of excessive amounts of calcium as a fixed base to get rid of acid radicles; and excessive parathyroid hormone activity, leading to phosphorus diuresis, a low serum phosphorus level, undersaturation of the blood with respect to calcium and phosphorus, increased resorption of calcium and phosphorus from bone and, finally, hypercalciuria. Since there is no history in this case of polygalactodipsia (increase in milk intake), alkalophagia or acidosis, the first three of these causes will be dismissed.

Did the patient have hyperparathyroidism? If so, there was practically no bone disease, since the visible bones are of normal density and show no cysts, the lamina dura about the teeth is fairly well preserved, and the serum phosphatase level was practically normal (normal, 3 to 5 Bodansky units per 100 cc.), particularly if the slight dehydration is recalled. It has been well established by Dr. Fuller Albright, however, that hyperparathyroidism can exist with little or no bone involvement, presumably because the patient ingests sufficient calcium and phosphorus to maintain the blood saturation so that bone resorption does not occur. The serum calcium and phosphorus levels make a diagnosis of hyperparathyroidism attractive. The calcium levels of 11.1 to 11.6 mg. per 100 cc. are in the borderline range between normal and high values according to the laboratory methods in use before the fall of 1943 (normal, 9.0 to 10.5 mg.) and are definitely high according to the methods now in use (normal, 8.5 to 10.0 mg.). This patient was studied in 1942, so the serum calcium level must be judged by the old standard. When these values are corrected for the low serum protein level, they would average about 12.0 mg. or a little more; in other words, they would be unquestionably high. Furthermore, the serum phosphorus values were definitely low (normal, 3.0 to 4.0 mg. per 100 cc.), particularly if we recall that slight dehydration was present. The low serum phosphorus levels also make it clear that the overactivity of the parathyroid gland was primary and not secondary to renal disease, for in the latter situation the serum phosphorus level is high.

Further strong evidence in favor of hyperparathyroidism is the occurrence of nephrocalcinosis. This type of calcification in both kidneys rarely occurs except as a consequence of hyperparathyroidism. A somewhat similar picture, but with larger areas of calcification, has been observed in 2 cases with *Haemophilus influenzae* infection in the urine¹; this condition is quite rare, and there is nothing to suggest it in this patient. Other conditions with calcification in the pyramids, such as mercury poisoning, late rickets and focal deposits due to colon-bacillus infection, are also extremely rare; furthermore, they do not give the finely granular calcification seen in the films of the present case. The fact that the urinary calcium excretion was not abnormally high, as measured by the Sulkowitch test, is consistent with the diagnosis, since the specific gravity of the urine is fixed in a low range. It would be of interest in obtaining further support for the diagnosis of hyperparathyroidism to know whether the patient had complained of fatigue, polydipsia or polyuria, and whether he had lost weight.

In summary, the sequence of events seems to have been: hyperparathyroidism, probably due to a small parathyroid adenoma; nephrocalcinosis, with calcium phosphate deposits; and pyelonephritis possibly due to colon bacilli and nonhemolytic streptococci as a result of the attack of scarlet fever or of spread from the apical abscesses.

A brief word about treatment is in order. As a first step the parathyroid adenoma should be removed. Then efforts should be made to improve the kidney status. This type of calcification is not amenable to surgery, but retrograde dissolution of part of the calcification might be possible with Solution M (magnesium citrate solution buffered at a pH of 5).² There is still hope that an agent may be found that, taken by mouth, will tend to dissolve the calcium by creating an acid situation in the tubules. Of course, the urinary-tract infection must be kept under control during such a procedure. Even if no attempt is made to get rid of the calcification, an effort should be made to eliminate the urinary infection. Although this is difficult to do in the presence of calculi, it has been accomplished in several cases. In particular, this patient might have been one of those in whom penicillin causes a disappearance of nonhemolytic streptococci, and then colon bacilli, which occasionally are secondary invaders, may disappear spontaneously or in response to sulfonamide therapy.

DR. BENJAMIN CASTLEMAN: Dr. Colby, would you like to comment on this case?

DR. FLETCHER H. COLBY: We occasionally see patients like this, with calcification spread throughout the kidney in such a way that it involves the parenchyma rather than the calyces and pelves. I recently had a patient, a young man in the air

force, who presented a picture almost exactly the same as this. He had calcification spread throughout the parenchyma of both kidneys. The urine was strongly acid, and he had a colon-bacillus infection.

I was interested in Dr. Reifenstein's comments on the distribution of calcification in tuberculosis. My experience has been that calcification in tuberculosis is present anywhere in the kidney. When we see patients like this we always think that tuberculosis is one thing that we have to eliminate. I have always hesitated to eliminate tuberculosis simply on the x-ray appearance of the distribution of calcium. I may be entirely wrong, but I believe that one ought to depend entirely on guinea-pig inoculation to be sure that it is not tuberculosis, even though the patient has an accompanying streptococcal or colon-bacillus infection, which is frequent in tuberculosis.

It seems to me that we do not know the answer to this type of case, whether the disease starts as pyelitis and, as a result of long-continued renal damage, calcium is deposited or whether the calcium is deposited first as a result of the infection.

DR. FULLER ALBRIGHT: I did not know that tuberculosis would cause bilateral calcification so uniformly throughout the kidney. It is usually bilateral but not so smoothly spread.

DR. OLIVER COPE: As one would expect from what Dr. Reifenstein has said, exploration for an anatomic diagnosis was an inevitable requirement. We can sit and argue at this stage about the diagnosis but we need more positive evidence. Early operation is important from the patient's point of view because some of our best results in hyperparathyroidism have been achieved in patients who have had a mild degree of glandular disease with crippling kidney damage. The amount of kidney damage may be wholly disproportionate to the glandular dysfunction.

The surgeon likes to be asked to operate on patients with an unequivocally high blood calcium level, an unmistakably low phosphorus level and a great deal of calcium in the urine. In hyperparathyroidism, as Dr. Castleman³ has pointed out, the size of the offending parathyroid adenoma is directly proportionate to the increased level of ionized calcium in the blood plasma; in a patient with a blood calcium level of 14 mg. per 100 cc. or higher one knows that the surgical problem is simple because the offending gland or glands will be at least grape size and easy to identify. The surgeon approaches a patient of this type, one having a blood calcium level just above normal, with his heart in his mouth, and as you will see in this patient I was not able altogether to swallow my heart when I had finished. I shall read part of the operative note.

The right thyroid region was first explored. A small, thin, soft gland, the right upper, was found in a sulcus of the thyroid gland posteriorly, at the junction of the

middle and upper thirds. It was the brown color of an adenoma but was too small and thin. [The color of the gland depends on the proportion of fat to epithelial cells. If it contains no fat, it is brown; the more fat it contains, obviously the yellower it is. Normal glands vary. Adenomas generally have no fat in them.] The left side was then explored. Both the upper and lower were identified. The upper was asymmetrically placed, near the inferior thyroid artery. It was of the same brown color as the right upper but was larger and firmer. The left lower was grayer in color, longer and a little softer and lay posterior to the lower pole. The lower right region was next explored, and the gland was found. It was the largest, but was the gray-greenish color of the left lower. The right lower was excised, since it was thought to be an adenoma, but after removal it seemed more like a normal gland. The left upper was then excised as the likeliest to be an adenoma, the left lower and right upper remaining intact and unbiopsied.

Thus we found the four glands; the two upper ones were brown, and the two lower were a totally different color, the color of the largest gland not being consistent with adenoma. Within the normal-sized glands in such mild cases one can often find an adenoma that does not appear on the surface. Seemingly that is what we were confronted with here.

CLINICAL DIAGNOSES

Parathyroid adenoma.
Hyperparathyroidism.

DR. REIFENSTEIN'S DIAGNOSES

Hyperparathyroidism (parathyroid adenoma).
Nephrocalcinosis (calcium phosphate stones).
Pyelonephritis (colon bacilli and nonhemolytic streptococci).

ANATOMICAL DIAGNOSIS

Parathyroid adenoma (parathyroidoma).

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The gland that we received was quite small, and the size of the upper limit of a normal gland, and triangular. On microscopic examination, however, there was no doubt that it was an adenoma. There was a narrow rim of normal parathyroid chief cells and numerous fat cells surrounding the tumor, which had no fat cells and was composed of large water-clear cells. This type of tumor should probably be called not an adenoma but a parathyroidoma, because the cells do not form glands. This is one of the less frequent varieties of tumor that we see in this disease. The water-clear cells are enlarged vacuolated chief cells. In the usual type of adenoma, the chief cells are slightly enlarged and uniform in size and have a pale acidophilic cytoplasm. Another type is one that shows a bit more variation in the chromatin of the cells and sometimes has giant nuclei. This is the type that has been referred to by some pathologists as a parathyroid carcinoma. In our experience covering more than eighty tumors we have been unable to find a single example of parathyroid carcinoma. There have been no recurrences or evidence of metastases.

In a recent paper from the Mayo Clinic reporting 14 cases of hyperparathyroidism, 13, or 92.8 per cent, are called carcinomas.⁴ I believe that this paper gives the public the wrong impression of hyperparathyroidism, because this condition is benign, not malignant. Their interpretation is a bit weakened by a statement at the end, "In no case in the series under study did metastases or local recurrence occur." In other words, the diagnosis was wholly based on the morphology of the cell. The evidence for the malignant character of these tumors, according to the Mayo Clinic pathologists, rests on hyperchromatism and irregularity of the size of the nuclei. They show no definite mitoses in their photomicrographs. We have seen this same irregularity in staining character and in the size of the nuclei but do not believe that this justifies tagging a patient with carcinoma. In addition, the benignity of the disease is well borne out by the results.

A true carcinoma of the parathyroid gland can occur. Most of these, however, are nonfunctioning. In the Mayo Clinic report, reference is made to the fact that a review of the literature disclosed 7 cases of functioning parathyroid carcinomas. Two of these were from the Mayo Clinic and were included in the series of 14. This leaves only 5 cases outside of the Mayo Clinic. Some time ago Dr. Cope and I reviewed the reports of these 5 cases and concluded that only 2 of them^{5,6} were definitely malignant. It would be extremely unusual, therefore, to find carcinoma in 92.8 per cent of one series — that of the Mayo Clinic — and only 5 cases, less than 2 per cent, in the rest of the 300 reported cases. I have dealt with this aspect of the disease because I do not want you to go away with the idea that hyperparathyroidism is caused by a parathyroid carcinoma; it should still be considered a benign condition.

DR. FULLER ALBRIGHT: This case is an example of a tiny tumor, no bigger than a normal gland, that caused hyperparathyroidism. I think the point is that a normal gland is three quarters fat and one quarter epithelial cells, whereas a tumor is entirely composed of epithelial cells.

DR. CASTLEMAN: I might add that I have received a letter from this patient's physician stating that in November, 1944, more than two years after operation, the patient's general health was excellent and that he was regularly doing heavy work. It is interesting, however, that the urine was cloudy and that x-ray films still showed calcific deposits in the tubules.

DR. COPE: I am glad that Dr. Castleman has dealt with the question of carcinoma in these parathyroid tumors. I am astounded at the position taken by the physicians of the Mayo Clinic. They are calling the common benign adenoma malignant. The surgical implications that they draw are inordinate. Widespread excision, which one likes to practice in malignant disease, would be crippling to the patient.

CASE 31092

PRESENTATION OF CASE

First admission. A thirty-four-year-old accountant was admitted to the hospital after a convulsion.

Sixteen years previously, at the age of eighteen, and many times since then, he had been refused life insurance because examination of urine revealed albumin, casts and a low specific gravity. At that time eight different physicians saw him in rapid succession and treated him with "bladder irrigations." At the age of twenty he was admitted for two weeks to another hospital, where he was cystoscoped, following which he had weekly bladder irrigations for one year. At twenty-seven he was placed on a salt-free, low-protein diet, which he disregarded. At twenty-nine he was admitted for two weeks to still another hospital, where he was given sulfathiazole, which "cleared up" the urinary-tract infection. He was apparently well for the next five years. Five months before admission he experienced severe muscular cramps in the calves and upper abdomen. At that time his physician gave him calcium lactate and iron tablets and three months later added one quart of milk daily. Two weeks before admission he developed a head cold with coryza, severe hoarseness and cough productive of bloody mucus. He spent three days in bed, the oral temperature being 102°F. While in bed his muscle cramps returned. Two days before admission he experienced two episodes of shaking of the extremities and body without loss of consciousness but with inability to grasp anything and with resultant pain and tenderness of the muscles. In the afternoon of the day of admission, while standing at a gasoline station, he had another episode of generalized shaking and fell to the ground unconscious, following which he was brought to this hospital.

At fourteen years of age he had had a tonsillectomy, and at eighteen he had been treated for gonorrhea with irrigations. He had been married twice and had two children, six and nine years of age respectively.

Physical examination revealed a well-developed, well-nourished, man showing deep regular respirations. The throat was red. The right side of

the tongue was swollen and bruised. The nasal mucosa was covered with dried hemorrhagic exudate. A few petechiae were present over the upper thorax. Breath sounds were slightly increased, with fine rales in both axillas. An apical Grade II systolic murmur was heard. The muscles were diffusely tender. A uremic odor was noted on the breath. Trousseau and Chvostek signs were negative.

The temperature was 98.6°F., the pulse 90, and the respirations 20. The blood pressure was 160 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 2,380,000, with 6.6 gm. of hemoglobin. The white-cell count was 14,700, with 77 per cent neutrophils. There was moderate variation in size and shape of the red cells. The urine was light amber and acid in reaction. The specific gravity ranged from 1.008 to 1.012, with one later specimen reaching 1.020 and one 1.004. There was a ++ test for albumin. The sediment showed 1 to 3 white cells and occasional red cells per high-power field. A Hinton test was negative. The nonprotein nitrogen was 120 mg. per 100 cc. The total protein was 5.5 gm., with an albumin-globulin ratio of 2.5. The serum sodium was 131 milliequiv. per liter, the chloride 106 milliequiv., the carbon dioxide 7 millimols, the calcium 8.6 mg. per 100 cc., the phosphorus 7.5 mg., the potassium 5.7 milliequiv. per liter, and the phosphatase 4.9 Bodansky units per 100 cc. A phenolsulfonephthalein test showed less than 10 per cent excretion in one hour. Urine culture on admission grew a few colonies of *Staphylococcus albus*. X-ray films of the abdomen were negative.

On the twelfth day the patient was put on intramuscular penicillin — 48,000 units per day for four days, 24,000 units for two days and 12,000 units for six days. Subsequent urine cultures showed no growth. On the nineteenth day he had had a severe pain in the chest, which one observer believed was characteristic of coronary occlusion. An electrocardiogram was negative. During treatment the carbon dioxide reached 31.2 milliequiv. per liter but fell back to 17 milliequiv. The serum phosphorus was elevated to 11.4 mg. per 100 cc. The nonprotein nitrogen did not change.

The patient was discharged on the thirty-fifth hospital day; he felt quite strong and much improved. During his stay he had received six 500-cc. transfusions of whole blood, as well as Citro-carbonate and calcium gluconate.

Second admission (two months later). Six weeks after discharge he had an episode of severe nocturnal dyspnea. He promptly developed congestive failure but responded well to digitalization. Ten days before admission he developed a cold, with fever and a cough productive of blood-tinged sputum, and a week later had another episode of severe dyspnea. During the following two days he became increasingly drowsy, continued to cough, was nauseated, vomited and had slight pain in the right chest.

Physical examination revealed a pale, dehydrated, drowsy, orthopneic man sitting upright in obvious distress; he had a strong uremic odor on his breath. The heart was enlarged in all directions. The sounds were weak, with a gallop rhythm at 120. The lower two thirds of the right chest showed dullness and diminished breath sounds and tactile fremitus. Moist rales were heard bilaterally. The pain in the right chest was severe. The liver was palpable three fingerbreadths below the costal margin. There was moderate ascites, and marked edema of the sacrum and lower extremities.

The temperature was 101°F., and the respirations varied between 20 and 35. The blood pressure was 210 systolic, 100 diastolic.

Several attempts to withdraw fluid from the right chest failed. A pericardial friction rub was constantly present after the third day. The urine was alkaline, with a specific gravity of 1.007, a + test for albumin and a few red cells and white cells in the sediment. The blood revealed a white-cell count of 44,200, with 99 per cent neutrophils, and a red-cell count of 1,840,000, with 5 gm. of hemoglobin. The nonprotein nitrogen was 200 mg. per 100 cc., the carbon dioxide, 12 to 15 millimols per liter, the chloride 91.0 milliequiv., the calcium 8.1 mg. per 100 cc., and the phosphorus 6.5 mg. Urine culture grew *Staph. albus* and nonhemolytic streptococci. The blood and sputum showed Type 1 pneumococci.

The patient was treated with intravenous fluids, sulfadiazine, transfusions, Mercupurin, digitalis, calcium gluconate, Hykinone and sedative drugs. The sulfadiazine blood level never exceeded 10 mg. per 100 cc., and the urinary output did not drop. His sensorium gradually became increasingly clouded. He was comatose and died on the eighth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM W. BECKMAN: It seems to me that three diseases contributed to this man's death. One of them was acute and terminal. Another, hypertensive heart disease with congestive failure, was a sequela of the third, chronic renal disease. Certainly there is enough evidence to make a diagnosis of chronic nephritis of some sort. He had a long history of continuous albuminuria, low specific gravity and casts in the urine. He evidently was having symptoms during most of this period because he consulted so many physicians.

On physical examination there was the additional finding of high blood pressure. The laboratory findings of marked anemia, albuminuria, elevated nonprotein nitrogen, elevated serum phosphorus and marked acidosis all confirm the diagnosis of chronic nephritis. It is of interest that the casts had disappeared from the urine by the time he came to this hospital. This of course is to be expected, for, as chronic nephritis progresses into the terminal stage,

the formed elements in the sediment usually diminish and frequently disappear.

One must always attempt to define the kind of nephritis. This differential is usually more academic than practical, but it has gained importance as various sorts of chemotherapy have been devised to treat pyelonephritis according to the type of infecting organism. The wide range of the specific gravity, from 1.004 to 1.020, is surprising, for one would expect a fixed specific gravity in the terminal stage of the disease. No correction was made for the albumin, however, and it is well known that unless such a correction is made the specific-gravity readings may vary markedly. There is little here to suggest glomerulonephritis. He had had a tonsillectomy, but he had had no evidence of a streptococcal pharyngitis, scarlet fever or anything that tends to dispose toward the development of glomerulonephritis. Everything seems to point to the fact that he had pyelonephritis. It would be interesting to know whether he consulted a physician at the age of eighteen for gonorrhea before he was refused life insurance, owing to albuminuria. If this had been the case it is possible that the local irritation occasioned by the irrigations might have started an infectious process in the genitourinary tract. Following the onset, whatever it was, his many physicians all seemed to think that he needed the various sorts of treatment for the urinary-tract infection that were used. He was given bladder irrigations before the time of chemotherapy, and when chemotherapy came along, he was given sulfadiazine, which was said to clear up the infection. Probably it did not. He did well following this form of treatment and had five years of freedom from symptoms. This was probably because he had become accustomed to his chronic nephritis rather than because it had been cured, although there is no way of proving that. At any rate, I think that pyelonephritis is the likeliest explanation for the chronic renal disease.

The fact that he had pains in the legs and abdomen and had an attack of pain in the chest, which was thought to be characteristic of myocardial infarction, and the fact that he had cerebral manifestations in the form of convulsions make me wonder about some generalized vascular disease, such as periarteritis nodosa. Certainly all these are symptoms of that syndrome, and in addition it would explain the petechial rash that he had at the time of the first admission. Otherwise I cannot explain the rash. One does get all kinds of skin manifestations in periarteritis nodosa. I think it unlikely, however, that a person with periarteritis nodosa could go for sixteen years with only albuminuria, and little else, to show for it. We are following one patient with periarteritis nodosa, proved by biopsy, of many years' duration who shows nothing but albuminuria. That is most unusual. Anyway, if a patient has chronic pyelo-

nephritis he has a good right to a general vascular disease in the form of plain arteriosclerosis, and I should think that that is the more probable in this case.

It is worth considering the nature of the convulsions. In uremia there are two varieties — those due to hypertensive encephalopathy and those due to tetany resulting from a low serum calcium. The low calcium in this case is probably associated both with a lowered serum protein and with definite phosphate retention. Incidentally in situations like this, when there is chronic phosphate retention, the parathyroid glands are almost invariably found to be hypertrophied. This has been interpreted to mean that these glands are working overtime in an effort to correct the derangement in calcium and phosphorus in the serum. A total calcium of 8.6 mg. per 100 cc. is hardly low enough to produce tetany, particularly in the presence of such a high degree of acidosis as is indicated by the carbon dioxide of 7 millimols per liter. Therefore, I should say that the convulsions were on the basis of hypertensive encephalopathy, although I do not know what that is.

We then come to the treatment with penicillin. That is something not too commonly done in uremia. I have a similar patient, a man with chronic uremia whom I have followed for seven years. His urine culture always grows *Staphylococcus albus*. I asked Dr. Forbes about treating him with penicillin, and she replied that it would certainly be an advisable thing to do. It might be well to have Dr. Forbes comment on that now.

DR. ANNE P. FORBES: My statement was based on the fact that we know that a chronic renal infection can lower kidney function. Since these patients have little renal tissue to spare, getting rid of the infection may relieve them of a burden that might otherwise be crippling.

DR. BECKMAN: Whether it was due to penicillin, — he received a number of other things, — the patient improved and went home feeling better. It is interesting that they treated him with alkalis in the presence of the low calcium. Alkalosis, of course, tends to accentuate any tendency to tetany. I suppose that the addition of calcium gluconate was meant to take care of this eventuality.

The attack of nocturnal dyspnea indicates that the patient had developed hypertensive heart disease and congestive failure. Although his failure improved somewhat at first it was quite definitely manifest when he came into the hospital the second time.

The final episode clearly appears to be a Type 1 pneumococcus infection of the lungs and blood stream. It is not easy to take care of such a pneumococcal infection in the presence of chronic renal disease. In addition to the therapeutic problem presented by the necessity of giving chemotherapy and fluids to a person with chronic renal disease

who is in congestive failure, another dilemma is encountered. The chronic renal disease makes it much more difficult for the body to take care of the infection, and at the same time the acute infection tends to accentuate the renal failure.

I think that this patient died of Type 1 pneumococcus infection, both in the lungs and in the blood stream, of chronic pyelonephritis, with renal failure, and of hypertensive heart disease, with severe congestive failure. I should have pointed out that I believe the large liver and the ascites were on the basis of congestive failure and that the pericardial friction rub indicates a terminal uremic pericarditis.

DR. JACOB LERMAN: While the patient was being treated in the hospital, we talked a bit about the cause of the tetany and I thought definitely when the patient was first admitted that the tetany was due to overbreathing. I do not believe we settled that point. In any case the patient got better and was treated with alkalies and calcium and the convulsions did not return.

CLINICAL DIAGNOSIS

Chronic pyelonephritis.
Lobar pneumonia, Type 1.

DR. BECKMAN'S DIAGNOSES

Chronic pyelonephritis.
Uremia.
Pneumonia and septicemia (Type 1 pneumococcus).
Hypertensive heart disease.
Pericarditis, terminal, uremic.
Congestive heart failure.

ANATOMICAL DIAGNOSES

Chronic pyelonephritis, bilateral.
(Uremia.)
Pleuritis, pericarditis and peritonitis, acute fibrinous, with effusion (Type 1 pneumococcus).

Septicemia (Type 1 pneumococcus).

Parathyroid hyperplasia, marked, secondary.
Cardiac hypertrophy, hypertensive type.
Peripheral edema.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy of a man showed that the terminal infection was a Type 1 pneumococcus septicemia, with a shaggy fibrous pericarditis, pleuritis and peritonitis, in other words, an acute fibrinous serositis. I do not believe I have ever seen all three serous cavities affected by the pneumococcus before. I suppose that the infection started in the lung, although at the time of the autopsy we were unable to find anything definite in the lung. If there had been pneumonia, it would have resolved. The parenchyma just under the pleura showed slight chronic pneumonitis, which may have resulted from the pleurisy, although it is quite possible that there had been a localized pneumonia. The kidneys were quite small, one weighing 56 gm. and the other 90 gm. They were markedly contracted and pale and showed the characteristic picture of pyelonephritis. There was marked destruction of the tubules and glomeruli and extensive infiltration with lymphocytes and polymorphonuclears. There were tubular atrophy and compensatory hypertrophy.

Long-standing chronic renal disease frequently produces secondary hyperplasia of the parathyroid glands, and in this case all four were tremendously enlarged, weighing together almost 5 gm., which is about thirty to forty times their normal weight. They were pale gray in contrast to the brown color that one sees in primary parathyroid adenoma. Microscopically there was an increase in the number of normal-sized cells rather than the hypertrophy of individual cells that is seen in an adenoma. There was obliteration and replacement of all the fat. The heart was enlarged, weighing over 500 gm.

SEVENTY-FIFTH ANNIVERSARY

It is not every day that a state department of health can celebrate a diamond jubilee. In fact, it has never happened in America until now. This issue of the *Journal* carries an article outlining the history of the Massachusetts Department of Public Health during the past seventy-five years, stressing in particular the contributions made by certain outstanding medical men.

At the time of the founding of the Massachusetts State Board of Health in 1869, the term "public health" meant very little in this country. Measures for the control of communicable disease were based on beliefs rather than on knowledge. Robert Koch

and Louis Pasteur had not yet revolutionized the prevailing ideas on the causation of disease. Only in the case of smallpox was there an effective method of immunization. Public water supplies were far from safe. Sewage disposal was still largely a matter of individual rather than community responsibility.

The newly created State Board of Health attacked these problems with courage and wisdom. They pioneered so broadly and so successfully that a lasting impress was left on sanitary practice in this and even in other countries. This was made possible largely because of a group of extraordinary individuals, who devoted their best energies to the task. Chief among these early pioneers were Dr. Henry I. Bowditch, Dr. Henry P. Walcott and Dr. Theobald Smith, honored names in Massachusetts medical history.

The period from 1869 to 1914 has well been called the "era of sanitation." By the end of that period, tremendous strides had been taken through the energetic programs of Mills, Sedgwick, Goodnough and other engineers and the time was ripe for entry into new fields. When the board was succeeded by the Department of Health in 1914, which became the Department of Public Health in 1919, an expansion in the perspective of the public was taking place and new tasks were undertaken.

Emphasis in the control of communicable diseases shifted to prevention through the use of biologic products. Education of the public in matters of hygiene was recognized as a necessity. Dr. Allan J. McLaughlin, Dr. Eugene R. Kelley, Dr. George Bigelow and their successors, following in the footsteps of the original board, kept the department well up in the front line of advance in public-health knowledge and practice. Indeed, on various occasions the department led the advance, as in the cancer-control program and that for the study and control of tuberculosis in children. A constant stream of visitors from all over the world to observe the workings of an established state health organization has testified to the department's standing.

It is especially interesting to study the relation of state to local administration in Massachusetts in view of the strong home-rule tendencies of this state. The department's functions have been mainly advisory, rather than supervisory, from the beginning.

Its seventy-five years' experience furnishes material for a study of decentralized health administration, as contrasted with the more centralized forms of many other states. Some of the inadequacies of the decentralized system are apparently now coming to light as problems become more complicated because of the widening scope of medicine and public health and the increasing density of population. An arrangement that functioned satisfactorily in pioneering days may prove inadequate to cope with the problems of the future.

MATERIA MUSICA

THE Massachusetts General Hospital in 1941 opened the doors of its new chapel, the creation of which was the "postscript" of Bishop Lawrence's long and useful life. A Hammond organ became part of the equipment of this nonsectarian sanctuary, and to it has been added an electrical record player of high quality. With also a portable instrument that can be taken to the wards, the hospital has at last, within this decade, achieved musical independence as a long step forward from the time when hired or volunteer talent was brought to its corridors on infrequent occasions.

A program is now in effect whereby regular organ recitals and occasional gatherings of whoever will for singing exercises are augmented by short concerts of electrically transcribed music at established hours each week. In this way is the chapel, although used for no set services, still further fulfilling the broad purposes of its founder.

The next step in the musical education of the institution has been, and will continue to be, the collection of a library of records — an enterprise that has gone forward surprisingly well as its needs were made known. Although now under the guidance of a music committee, this new activity is in the hands of the Occupational Therapy Department — fittingly enough, if it is conceded that the minds and emotions should be as well occupied as the hands.

No one will question the therapeutic value of music or the possibilities for its use in the hospital armamentarium that the future may bring. In the meantime the Massachusetts General Hospital

may be congratulated on the opportunities that it has been able to make available for patients and personnel, with our best wishes for continuing success in this cultural project.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BISHOP — William A. Bishop, M.D., of Watertown, died February 14. He was in his fifty-seventh year.

Dr. Bishop received his degree from Tufts College Medical School in 1913. He was a widely known authority in the field of industrial medicine, and for the past fifteen years had served as medical director for the American Mutual Liability Insurance Company. During World War I, Dr. Bishop served as a captain in the Army Medical Corps. He gave up his private practice last October but had continued as associate physician on the staff of the Massachusetts General Hospital. He was a fellow of the American Medical Association.

His widow and a daughter survive.

SHAUGHNESSY — M. James Shaughnessy, M.D., of Framingham, died February 17. He was in his sixty-fourth year.

Dr. Shaughnessy received his degree from Harvard Medical School in 1907.

His widow survives.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

EMERGENCY MATERNITY AND INFANT CARE PROGRAM

CONSULTANTS IN PEDIATRICS

There has been a change in the procedure concerning payment to pediatric consultants participating in the EMIC program.

The department is no longer permitted to pay a consultant's fee to a pediatric consultant when he signs the pediatric application, because he then becomes the attending physician and must be paid as attending physician according to the fee schedule. A pediatric consultant is considered to be the attending physician when the case is turned over to him for care by another physician or when the mother goes directly to him for the care of her infant.

A consultant in pediatrics who expects to be paid as a consultant should make sure that the pediatric application is signed by the attending physician and that he names the pediatric consultant on the application. The pediatrician may then be paid as a consultant to the attending physician when services are rendered.

CO-OPERATION REQUESTED IN BLINDNESS PROGRAM

Attention is called to the law requiring the reporting of blindness in any patient examined at a clinic,

hospital or other institution or by a private physician or optometrist.

Such information is indispensable as a foundation for the development of a sound constructive program for preventing blindness in Massachusetts. As complete knowledge of the causes of blindness is vitally necessary, the co-operation of all physicians is urged in observing the law, which is as follows:

Chapter 69, General Laws, Section 19A: Whenever, upon examination at a clinic, hospital or other institution, or elsewhere, by a physician or optometrist, the visual acuity of any person is found to be with correction 20/200 or less in the better eye, or the peripheral field of his vision to have contracted to the ten degree radius or less regardless of visual acuity, the superintendent of such institution, or the physician, optometrist or other person who conducted or was in charge of the examination if it took place elsewhere than in such an institution, shall within thirty days report to the director the result of the examination and that blindness of the person examined has been established.

Such information should be forwarded to: Arthur F. Sullivan, Director, Division of the Blind, Department of Education, 110 Tremont Street, Boston 8. A supply of report forms may be obtained from the same address.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR JANUARY, 1945

RÉSUMÉ

DISEASES	JANUARY 1945	JANUARY 1944	SEVEN-YEAR MEDIAN
Anterior poliomyelitis	2	1	1
Chancroid	3	0	*
Chicken pox	1798	2512	2528

Whooping cough	613	373	881

*Made reportable December, 1943

†Pfeiffer-bacillus meningitis only other form reportable previous to 1941

COMMENT

Bacillary dysentery, during January, showed a marked increase in the number of cases, reaching a figure more than three times that of December and seven times that of the seven-year median.

Scarlet fever reached the highest point for any January since 1933. The cases were well scattered throughout the Commonwealth.

Lobar pneumonia dropped to the lowest January figure since reporting began.

For the second time in history no cases of typhoid fever were reported in the month of January.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Haverhill, 1; Lowell, 1; total, 2.

Anthrax was reported from: Lynn, 1; Peabody, 1; total 2. Diphtheria was reported from: Barnstable, 1; Boston, 3; Foxboro, 1; Hull, 1; Mattapoisett, 1; Medford, 1; New Bedford, 1; Somerville, 9; Southbridge, 1; Waltham, 1; total, 20.

Dysentery, bacillary, was reported from: Beverly, 3; Boston, 7; Cambridge, 3; Lexington, 19; Malden, 2; Quincy, 1; Revere, 1; Wakefield, 4; Walpole, 1; West Boylston, 2; total, 43.

Encephalitis, infectious, was reported from: Chelsea, 1; Everett, 2; Somerville, 1; total, 4.

Malaria was reported from: Boston, 4; Camp Edwards, 8; Cushing General Hospital, 14; Haverhill, 4; Hingham, 1; Lowell, 1; Medford, 1; Melrose, 1; Quincy, 1; Regional Hospital, Waltham, 31; Somerville, 1; Webster, 1; total, 68.

Meningitis, meningococcal, was reported from: Boston, 8; Chelsea, 1; Chicopee, 1; Fall River, 1; Fitchburg, 1; Haverhill, 2; Lynn, 1; Marblehead, 1; Medford, 1; Naval Training School (Harvard University), 1; Plymouth, 1; Quincy, 1; Revere, 1; Wakefield, 1; Worcester, 1; total, 23.

Meningitis, Pfeiffer-bacillus, was reported from: Boston, 1; Bourne, 1; Salem, 1; total, 3.

Meningitis, pneumococcal, was reported from: Newton, 2; Springfield, 1; Worcester, 1; total, 4.

Meningitis, other forms, was reported from: Boston, 1; Lynn, 1; Tisbury, 1; Watertown, 1; total, 4.

Meningitis, undetermined, was reported from: Boston, 2; Chelsea, 2; Monson, 1; total, 5.

Salmonella infections were reported from Arlington, 1; Cambridge, 1; Melrose, 1; total, 3.

Septic sore throat was reported from: Attleboro, 1; Boston, 19; Everett, 1; Merrimac, 6; Millbury, 1; Norwood, 1; Watertown, 1; Whitman, 1; total, 31.

Tetanus was reported from: Grafton, 1; total, 1.

Trichinosis was reported from: Becket, 1; Boston, 4; Chelsea, 1; Shirley, 1; total, 7.

Undulant fever was reported from: Amesbury, 1; Boston, 1; total, 2.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Lowell	March 2	Albert H. Brewster
Salem	March 5	Paul W. Hugenberger
Haverhill	March 7	William T. Green
Brockton	March 15	George W. Van Gorder
Worcester	March 16	John W. O'Meara

Springfield	March 21	Garry deN. Hough, Jr.
Fall River	March 26	Eugene A. McCarthy
Hyannis	March 27	Paul L. Norton

MISCELLANY

ABSENTEE SICKNESS RATE SOARS

Absenteeism due to sickness among male industrial workers showed a substantial increase for the third quarter of 1944, shooting the total industrial sickness rate for the year up to 37 per cent above average for the period 1935-1944, according to statistics released by the Industrial Hygiene Division of the United States Public Health Service.

Nonrespiratory-nondigestive diseases rose 15 per cent above the same period in the previous year. Conditions contributing to this record included a 26 per cent increase in "rheumatism," a 29 per cent increase in neurasthenia and other diseases of nervous or mental origin and a 34 per cent increase in diseases of the genitourinary system. The incidences of rheumatic diseases, diseases of the heart and arteries, nephritis and nervous diseases have never been equaled or exceeded within the past decade. Nervous

diseases showed the highest rate of increase, rising 76 per cent above the ten-year mean. The rate of respiratory diseases, although slightly lower than that in 1943, was 32 per cent above average for the decade. Digestive diseases also rose to a rate exceeding anything experienced within the ten-year period.

Employment conditions peculiar to wartime are held responsible. Categories of disease showing the highest increase involve mainly older workers. The hiring of workers long unemployed or retired is one factor held to contribute to the record sickness rate, as is the employment of youths and other inexperienced personnel, and the necessity for employing in industry men rejected by the armed services. Wartime working and living conditions are also thought to be reflected, since other factors held accountable include emotional strain and personal mental conflict, overcrowding in plants and war communities, fatigue due to the lengthened work week, and night work. — Reprinted from *Industrial Hygiene News Letter* (January, 1945).

CORRESPONDENCE

PHYSICIANS REGISTERED IN NOVEMBER

To the Editor: Attached is a list of the physicians registered by examination by the Massachusetts Board of Registration in Medicine on November 17, 1944.

H. QUIMBY GALLUPE, *Secretary*

* * *

- Addes, Jacob (Middlesex University, 1944): 5123 14th Avenue, Brooklyn, New York.
 Agrin, Irving Nelson (Chicago Medical School, 1943): 3053 36th Street, Astoria, Long Island, New York.
 Becker, William (Chicago Medical School, 1943): 404 Hart Street, Brooklyn, New York.
 Berkowitz, Moe (Middlesex University, 1943): 1319 Avenue P, Brooklyn, New York.
 Boller, Raymond Jerome (New York University, 1942): 51-11 63rd Street, Woodside, Long Island, New York.
 Camelio, Albert Patrick (Boston College of Physicians and Surgeons, 1944): Holy Family Hospital, Brooklyn, New York.
 Coggan, Manuel (Middlesex University, 1943): 84 Mt. Vernon Street, Malden.
 Dorsey, Joseph Farrell (University of Tennessee, 1937): 1221 Forrest Avenue, Memphis, Tennessee.
 Ehrenberg, Bernard (Chicago Medical School, 1943): 632 Union Avenue, Elizabeth, New Jersey.
 Eyres, Alfred Ernest (State University of Iowa, 1932): Worcester State Hospital, Worcester.
 Fitch, Edna Mae Jones (University of Wisconsin, 1943): Sturgis, South Dakota.
 Gelbin, Milton Ruel (Chicago Medical School, 1943): Barnet Memorial Hospital, Paterson, New Jersey.
 Goldstein, Max Richard (Hahnemann Medical School, 1943): 605 Commonwealth Avenue, Boston.
 Henry, Herman Gordon (Philadelphia College of Osteopathy, 1943): 35 W. Main Street, North East, Pennsylvania.
 Hindle, Joseph Anthony (Jefferson Medical College, 1940): Boston Psychopathic Hospital, 74 Fenwood Road, Boston.
 Hughes, Paul William (College of Physicians and Surgeons, Boston, 1944): 936 N. Irving Avenue, Scranton, Pennsylvania.
 Jacobs, John Lesh (Harvard Medical School, 1929): West Townsend, Vermont.
 Kennedy, Raymond James (Loyola University, 1926): 509 Third Avenue, Joliet, Illinois.
 Lazarus, Sydney Simon (Chicago Medical School, 1943): 300 Ocean Parkway, Brooklyn, New York.

 Wein, Eber Abraham (Chicago Medical School, 1943): 565 Manhattan Avenue, New York City.
 Weissman, Morris Paul (Middlesex University, 1942): 1395 Eastern Parkway, Brooklyn, New York.
 Woronoff, Morris (Middlesex University, 1943): 570 Lefferts Avenue, Brooklyn, New York.

NOTICES

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MARCH 8

FRIDAY, MARCH 9

- *9:00-10:00 a.m. Protein Nutrition in Problems of Medical Interest. Dr. Frederick J. Stare. Joseph H. Pratt Diagnostic Hospital.
 10:50 a.m. Tuberculosis of the Skin. Dr. G. Morris. (Postgraduate clinic in dermatology and syphilology.) Amphitheater, Mallory Building, Boston City Hospital.
 12:00 m. to 1:00 p.m. Clinicopathological conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

SATURDAY, MARCH 10

- *10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, MARCH 12

- *12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, MARCH 13

- *12:15-1:15 p.m. Clinicorontgenological conference. Peter Bent Brigham Hospital.

WEDNESDAY, MARCH 14

- *9:00-10:00 a.m. The Glaucoma Problem and General Medicine. Dr. Joseph Igersheimer. Joseph H. Pratt Diagnostic Hospital.
 *12:00 m. Clinicopathological conference. Children's Hospital.
 *12:00 m.-1:00 p.m. Clinicopathological conference. Cambridge Hospital.
 7:15 p.m. Graduate seminar in pediatrics. Children's Medical Service. Amphitheater 3A, Massachusetts General Hospital.

*Open to the medical profession.

- MARCH 8. Certain Neurological Problems as Regards Children: Diagnosis and treatment. Dr. Franc D. Ingraham. Pentucket Association of Physicians. 8:30 p.m. Haverhill.
 MARCH 14. New England Pediatric Society.
 APRIL 30. New York Institute of Clinical Oral Pathology. Page 120, issue of January 25.
 MAY 22-24. Hotel Statler, Boston. Annual meeting of the Massachusetts Medical Society.
 SEPTEMBER 17. American Public Health Association. Page 752, issue of November 30.

DISTRICT MEDICAL SOCIETIES

PLYMOUTH

- MARCH 15. Goddard Hospital, Brockton.
 APRIL 26. Toll House, Whitman.
 MAY 17. Lakeville Sanatorium, Lakeville.
 All meetings will be held at 11 a.m.

WORCESTER

- MARCH 14. Worcester Memorial Hospital.
 APRIL 11. Hahnemann Hospital, Worcester.
 MAY 9. Annual meeting.

EPOCHS IN THE HISTORY OF THE WORCESTER DISTRICT MEDICAL SOCIETY*

ROY J. WARD, M.D.

WORCESTER, MASSACHUSETTS

WE ARE now living in an age of science. Of all the sciences none have affected the welfare and happiness of the ordinary man more than has the science of medicine.

At the time of the founding of the Worcester District Medical Society, whose one hundred and fiftieth birthday is being celebrated tonight, medicine was just beginning to feel its growing pains. For years, prior to 1794, periodic epidemics of smallpox, diphtheria, typhoid fever, cholera and yellow fever had swept over Europe and America, threatening the lives of everyone. Today, we no longer wilt before the ravages of such epidemics. We have learned to control pain, wound infection, hemorrhage and shock. Tuberculosis and pernicious anemia, which were always fatal, are now responding to treatment. It is my purpose to give a picture of this district in 1794, and to trace the part that the physicians of this community played in this remarkable achievement of medical science.

In preparation, I have reviewed historical papers from the pens of Drs. Samuel B. Woodward, Homer Gage, Lemuel F. Woodward, Albert C. Getchell, Lester C. Miller and Albert M. Shattuck. Dr. Thomas H. Gage wrote the first historical sketch in 1854, but intense search for it has failed to locate any copy. I am also indebted for the splendid help that I have received from the staff of the American Antiquarian Society and its director, Mr. Clarence D. Brigham. Dr. William F. Lynch, chairman of the Anniversary Committee, and Dr. John Fallon, the librarian, have aided in collecting material and have been generous in constructive criticism; both have been an inspiration.

On December 16, 1794, forty-one physicians assembled at the United States Arms Hotel to form the Worcester Medical Society. Thirty-six of them rode into Worcester on horseback. They came from as far west as the Connecticut River and as far east as Mendon. Only one of them, Dr. John Frink, of Rutland, was a member of the Massachusetts Medical Society, and only one ever had at-

tended a medical lecture or a medical school. They came as a protest against the Massachusetts Medical Society, which had limited its membership to seventy and in thirteen years had elected to membership only one man from west of Framingham.

Worcester, a town of 2000 inhabitants, was selected as the meeting place, not because of its size, — for Charlton and Sutton were larger, — but because it was on the stage route between Boston and New York, and because the United States Arms Hotel was the best hotel in the county. Except for the stage route, roads were very poor. Many were mere bridle paths. Only the wealthy owned a wheeled vehicle or chaise; hence, everyone walked or rode horseback.

The early records tell little about the medical problems discussed at the meetings of those days. It is known that they took the form of case reports, which today constitute a favorite method of presenting medical subjects. It is also known that Worcester County at that time was in the throes of an epidemic of smallpox, meningitis and dysentery, and that smallpox alone killed $\frac{1}{4}$ per cent of the population.

The study of medicine at the time of the founding of this society was almost entirely by the preceptor system. Harvard Medical School had been in operation for twelve years, but by 1793 had graduated only ten students,[†] so that the preceptor system was the only one available to the majority of students. Dr. Samuel B. Woodward in his oration before this society in May, 1893, gave an interesting story of the mechanics of that system that is worth quoting in its entirety.

Each . . . [student] had studied with a preceptor, a plan not yet entirely given up as a part of a medical education, and at that time the only plan practicable.

A typical description shows that studying with a country doctor in 1793 meant chiefly "the care of the doctor's horse, doing chores about the house, assisting the instructor in gathering and drying the herbs and simples, preparing the porrett and the pills and, on rare occasions, helping in some minor surgical operations."

*By the act of Legislature incorporated the Massachusetts Medical Society in 1792, the Society was empowered to examine applicants for admission to practice medicine in the Commonwealth. Harvard Medical School was given the same right for its students.

[†]Twelve years after the founding of the Massachusetts Medical Society in 1792, the Society was empowered to examine applicants for admission to practice medicine in the Commonwealth. Harvard Medical School was given the same right for its students.

An indenture of 1760, quoted by Norwood, sheds such light upon the position of the apprentice, showing that the student's relations with his instructor were not in truth always and entirely one sided.

... during all which Term [four years and six months] the said Apprentice his said Master well and faithfully shall serve, his secrets keep, his lawful commands everywhere obey. He shall do no damage to his said Master, nor see it to be done by others, without letting or giving notice to his said Master. He shall not contract matrimony within said term. At cards, dice, or any other unlawful game he shall not play, whereby his said Master may have Damage. He shall not absent himself day or night from his said Master's Service without his leave, nor hant Ale houses, Taverns, or playhouses, but in all things, as a faithful Apprentice he shall behave himself toward his Master all during his said term. And the said Master, during the said term, shall by the best of his Means or Methods, Art and Mysteries of a Physician and Surgeon, as he now Professes Teach or cause the said Apprentice to be taught to perfection in consideration of the sum of One Hundred Pounds Lawful money of New York to him in hand paid. . . .

And the said William Clark acknowledges himself herewith contented and the Receipt thereof. And the said Master is to provide his said Apprentice with sufficient Meat, Drink, Washing and Lodging and Mending his said clothes, within the said term, and the said James Hubbard is to find him in wearing apparel during said term aforesaid. . . . At the end of Said term the Said Master shall and will give unto the Apprentice a new set of surgeons pocket instruments, Solomon's Dispensatory, Quences' Dispensatory, and Fuller on Fevers, and for the true performance of all and every of the said covenants: . . .

It was also customary to furnish the embryonic doctor with a certificate setting forth . . . "Mr. John Smith hath served as an apprentice to me for nearly four years, during which time he was constantly employed in the practice of Physics and Surgery, under my care, in which character he always behaved with great fidelity and industry. . . ."

Fortified with a like testimonial each man did set himself to work.

Dr. Austin Flint, of Leicester, was conducting a hospital in Worcester County for the inoculation of smallpox, and later was the first physician in the district to use the new method of vaccination with cowpox. Such subjects as these must have been uppermost in the members' minds and have made up the discussions of these early meetings. They were also looking into the future, for one of the most important actions of the newly formed society was to raise the educational requirements for the study of medicine, demanding a knowledge of Latin, Greek, elementary mathematics, natural history and natural philosophy.* This was just ninety years before Harvard Medical School required as much.

*Article 17 of the Laws and Regulations of Worcester Medical Society, adopted January 20, 1795, reads as follows:

"In order that the education of pupils should be more uniform and reputable it is the sense of this organization that before a person be qualified to enter upon the study of physick it is necessary that he have not only an accurate knowledge of his native tongue, but so much of the Latin and Greek as to translate them by the help of a dictionary, together with a knowledge of at least the elementary parts of mathematics, of natural history and of natural philosophy. . . . Before any pupil offer himself for examination, the physician who recommends him shall be certain that he has such a knowledge of anatomy as is necessary to understand the animal economy, its sound and morbid state, likewise an acquaintance with disease and the usual method of treating them, also a knowledge of the principles of chemistry, materia medica and the operation of medicine. As the art of physick is a mystery concerning which

In 1798 the problem came up of providing for a library, and Dr. Elijah Dix, an active physician, an apothecary and an extensive real estate dealer, offered to give 50 pounds to the society for the pur-

FIGURE 1. Daniel Waldo.

chase of books. This offer was accepted and a librarian was duly elected. Thus our library dates from this offer made in 1798, although Dr. Dix failed to keep his promise to provide the money for purchasing the books.

In 1804, after ten years' struggle with the Massachusetts Medical Society, that society's charter was so modified as to admit any respectable member of the profession. It also provided for district societies, and the Worcester Medical Society was the first one to join as a body.

In 1823, a campaign was started to raise a fund for more books for the library, and a generous subscription was received from Mr. Daniel Waldo (Fig. 1), a well-to-do merchant and importer owning

those who are not medically educated have not the means of judging so as readily to distinguish between the real physician and the imposing pretender, it appears highly reasonable that some criterion should be established by which those who are qualified for practice may be known, and in order, therefore, to prevent impositions whose consequences may prove so fatal and to assist mankind in forming a judgment in a matter to them so important, this Association declares it as their decided opinion that no physician ought to be encouraged in his profession unless he has passed an examination before some regularly appointed judges. The advantage of teaching physick by lectures is confessed by the usage of all Europe but has never been enjoyed among us until within a few years. We being persuaded that great advantage will result from such systematic mode of teaching all the branches of the medical art do hereby recommend to all such as are or may become our pupils to attend the medical lectures which are annually given at the University of Cambridge."

stores in Worcester and Boston. This was supplemented by a loan of fifty books from the Boston Medical Library. From then on the fortunes of this society rose and fell with the interest shown in the library. The records show that the library was moved from place to place because of the lack of a permanent home. When dust gathered on the books and they were scattered through the houses of the members, interest in the society also waned.

In 1845, Mr. Daniel Waldo left by will, among other benefactions, including a gift to the Mas-

sachusetts General Hospital, \$5000 to this society "for the purchase of costly but useful inventions for surgical purposes, and for books treating on medical subjects . . . to the end that the science of medicine . . . may be more fully understood and the community benefited by able and enlightened physicians and surgeons." The books purchased from this fund increased the problem of a suitable place to house them. Dr. John Green offered a room, free of rent for a year, over his apothecary shop, on Main Street. This is the same Dr. Green, who left the bulk of his fortune to found the Worcester Public Library. He evidently had his peculiarities, as illustrated by a sketch of the library room, Main Street (Fig. 2). His collection, Fig. 3, shows that he covered the whole medical field. It is also recorded that he, with a Dr. Nathan S. Green, sought to purchase medical material in England.

physician who came to town. Dr. Samuel B. Woodward is authority for the story that Dr. Homans, father of Dr. John Homans, of Boston, was one of these, and that Dr. Joseph Sargent was the first physician who succeeded in breaking down this monopoly.

At the opening of the Free Public Library in 1861 the books of the society were moved to comfortable rooms on the first floor, where there were ample bookshelves and room to hold the meetings. It was during this time that the library was considered the peer of any medical library in the country. It

FIGURE 2. A Characteristic Pose of Dr. John Green.

was in this location that the society flourished until 1850, when, owing to overcrowding, the books were moved to the attic. This was unfortunate. The space under the mansard roof was dingy, dirty and accessible only by a crooked elevator. There was not room enough for medical meetings, and the library died.

In 1922, the library was again asked to move. Under the leadership of the Library Committee, consisting of Drs. L. B. Marsh, Vincent L. Hunt and John Fallon, a new home was found at 34 Elm Street. It's struggle continued faced up the ready-made attic, but owing to lack of money most of the books were left lying in bundles in the basement. In a part of the restoration of the library a new corporation was formed, the Worcester Medical Library, Incorporated, including a number of the society.

In 1923, Dr. Green, in his second edition,

was in this location that the society flourished until 1850, when, owing to overcrowding, the books were moved to the attic. This was unfortunate. The space under the mansard roof was dingy, dirty and accessible only by a crooked elevator. There was not room enough for medical meetings, and the library died.

In 1922, the library was again asked to move. Under the leadership of the Library Committee, consisting of Drs. L. B. Marsh, Vincent L. Hunt and John Fallon, a new home was found at 34 Elm Street. It's struggle continued faced up the ready-made attic, but owing to lack of money most of the books were left lying in bundles in the basement. In a part of the restoration of the library a new corporation was formed, the Worcester Medical Library, Incorporated, including a number of the society.

In 1923, Dr. Green, in his second edition,

suggested a building to house the library and all the society activities, and he frequently suggested a site for such a building, but the time was not ripe. In 1935 he again made the same suggestion. Even

raised it still higher to provide a yearly nest egg. Thus, the members at home have pledged themselves to carry the financial burden for their comrades in arms.

In 1942 the library again moved. The trustees were in a dilemma. They searched the city for an available place. Many sites were found and abandoned because of expense. Then the Blood Bank Committee came forward with a proposition that the library share a small part of their building (Fig. 4), and sold to it one seventh of their building, in which it is now located, in crowded but useful quarters.

In 1906 a group of physicians and lay people organized, under the auspices of the Fresh Air Fund, the Clean Milk Stations Committee. Since mortality records were first kept it had been noted that the death rate among infants was extremely high during the summer months, and physicians were accustomed to postpone their vacations until the fall in order to care for the large number of gastrointestinal cases that were the cause of this mortality. The success of this initial effort to combat the disease was so obvious that the society voted to organize the Medical Milk Commission, to encourage the production of certified milk. This commission still is functioning and has been a large factor in saving hundreds of children's lives.

In 1936, this society blazed a new trail. Inspired by Dr. Arthur M. Kimberly, the *Worcester Medical News*, now under the guiding hand of Dr. Francis J. Steele, was started. It was the first modern district-society journal in Massachusetts and is now demonstrating its worth every month. Ninety years ago the Worcester Medical College published a medical journal extolling the virtues of the Thomsonian system of medicine, (Fig. 5).

It has been said that the modern hospital is the greatest clinical laboratory that society possesses, and that to it is owed most of the advances in medicine that have taken place. The Worcester District has not lacked in this respect. It has the first hospital ever built by tax funds for the care of the insane. This hospital was constructed by the State in 1832 on land provided by the city on Summer Street. Its first superintendent, Dr. Samuel B. Woodward, was the ancestor of the famous Woodward medical family, of whom the present Dr. Samuel B. Woodward survives. The latter is the authority for the following story of the opening of the hospital. Patients were admitted from all over the State—some from almshouses, jails and dungeons, where they had been kept under restraint. One man was brought chained inside of a wooden cage on a cart. When the new superintendent ordered the attendants to open the cage and unchain him, they remonstrated, but instead of attacking them, the patient knelt and raised his hands to worship Dr. Woodward, thinking that he must be God.

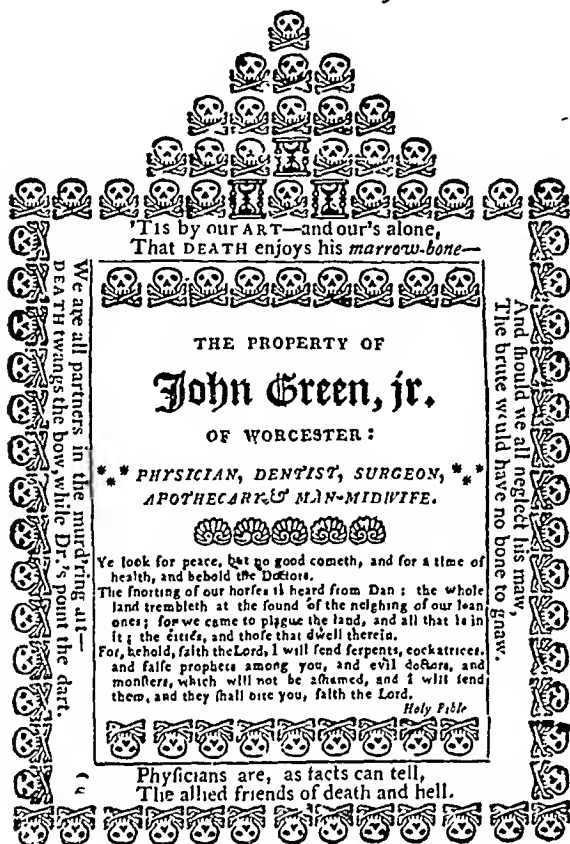

FIGURE 3. Dr. Green's Bookplate.

when the library was adequately housed at 34 Elm Street only half the members paid their dues. It was a battle to keep the rent paid, and only the most valuable of the magazines were bound. An \$18,000 appropriation was secured through the Works Progress Administration and the books were recatalogued and new stacks built, but finances continued to be a constant worry to the trustees. At their instigation a committee was appointed that, under the able leadership of Dr. Joel Melick, arranged a benefit lecture by Mrs. Franklin D. Roosevelt on "Peace." This was a financial success and was followed by three other benefits. These might have been continued had not the war intervened. More than \$6000 has been raised by this method, most of which has been put away for a building fund.

With the advent of the present war the problem of financing the activities of the society and the library increased. One third of the members had entered the armed forces. An unprecedented budget was brought in, large enough to cover not only the old but also some new activities. This was presented with trepidation, but the members themselves

In 1864, the United States Army opened the Dale General Hospital (Fig. 6) on Union Hill, occupying part of the buildings formerly used by the Worcester Medical College. Built to accommodate 1000 beds and with fourteen one-story wards, it was never filled. It was later abandoned after a vain attempt was made by the Federal government to have the city or state take it over. In 1867, Reverend John J. Powers opened a small hospital that was operated by the Sisters of St. Anne's Convent—interestingly enough, for poor patients who prepaid a small amount each year.

Dr. Peabody, former superintendent of the Worcester City Hospital, is the authority for the statement that it was done in the Clinton Hospital.

To Dr. Frank Washburn must be given the credit for establishing the Holden Cottage Hospital, a model of its kind and already so useful in its community that it is taxed beyond capacity.

Time does not permit enumerating the seventeen hospitals that have been established in this district since that early beginning on Front Street. Since then a magnificent system of hospitals has grown up all over the district, in large and small

FIGURE 4. Home of the Worcester Medical Library, Incorporated, and the Blood Bank.

In 1871, on the recommendation of Dr. Albert Wood, Worcester established the City Hospital at Front and Church streets, in the Abigail Bigelow House, with accommodations for eight or ten patients. Dr. Leonard Wheeler was the first superintendent and insisted on clinical records being kept, much to the displeasure of his visiting staff.

One of the first community hospitals to be started in the surrounding towns was at Clinton. In 1888, the Clinton Hospital Association opened its doors in a rented tenement for the admittance of its first patient, who promptly died. Discouraged but not disheartened, the association grew by dint of hard work, and now has an up-to-date hospital of seventy-four beds. Dr. Walter P. Bowers has been the president of the corporation for fifty years. Although there is some debate regarding where the first hysterectomy in the district was performed,

towns as well as in the city. Of the 6629 beds now available nearly half are outside the city limits. The rapid spread of community hospitals has added a great deal to the comfort and safety of the countryside.

The onset of the present war and the increasing use of blood for transfusions demonstrated the need of a supply for this district. At the January, 1942, meeting of the society, the pathologists of the city, Drs. Raymond Goodale, James Beck, William Moran and William Freeman, suggested the appointment of a committee to establish a blood bank. Headed first by Dr. Walter C. Seelye, and later by Dr. Edwin R. Leib, as president and Dr. William Freeman as secretary and director of the laboratory, the committee purchased a building, reconstructed it, installed equipment and has processed blood from 5000 donors. Both whole blood and blood plasma

are now distributed through twenty-four stations throughout southern Worcester County. The Cushing General Hospital at Framingham and the Lovell General Hospital at Fort Devens are

FIGURE 5. The Cover of an Issue of the Worcester Journal of Medicine.

also supplied. This outstanding voluntary effort on the part of the committee has been ably seconded by a splendid group of lay workers and donors, without whose aid it would have been difficult to carry on.

In 1869, the State Board of Health, the first of its kind, was established at Boston. Nine years later a city board was established in Worcester, with Dr. Rufus Woodward as the first secretary and executive officer. Since then, under the leadership of the medical profession, it has steadily increased its usefulness. One of our members, the late Dr. Thomas Kenney, was instrumental in reorganizing the setup. He built a \$1,000,000 addition to the Putnam Division of Belmont Hospital and pushed through, against considerable opposition, a plan for immunization of the school population against diphtheria, which has saved thousands of lives.

In 1894, the Health Department established a laboratory for the examination of sputums for

tubercle bacilli and cultures for diphtheria bacilli. This was the first municipal laboratory in New England and one of the first in the country after that begun in New York City. It was the beginning of a concerted attack on these two diseases in the district, which has led to remarkable results. A statistical study made some time ago revealed the fact that this city has been made the richer by \$10,000,000* over and above the cost of the department during the last twenty years because of the prevention of sickness and the saving of lives.

During the earliest days the Worcester District Medical Society met alternately in Rutland and Worcester. Later most of the meetings were held in various halls and clubrooms about the city, except in the period 1861-1899, when the meetings were held in the Worcester Public Library. It was often recorded that after the morning session the society adjourned for dinner at the American Temperance House on Foster Street (Fig. 7). For several years the society met occasionally at various hospitals, but a great stride forward was taken in 1923 when, during Dr. A. W. Marsh's presidency, the meetings were transferred to the hospitals in the district. This was a great boon to both interest and attendance.

With the multiplication of activities by the society the officers have come to lean more and more on the assistant to the librarian, first Mrs. Barbara McPherson and now Mrs. Marjorie Edwards. In addition to her duties in the Worcester Medical Library, the assistant is a great help to the secretary, the treasurer and the editor and business manager of the *Worcester Medical News*. Her services have been increasingly valuable to the whole society.

No history of the society would be complete without at least mention of some of the controversies that took place. Opposition to homeopathy and eclectic medicine raged in Worcester as it had all over the country for twenty-five years, from 1852 to 1877. Many men were expelled from the society for practicing these systems or consulting with their practitioners.

In 1845, Dr. Calvin Newton, a graduate of Berkshire Medical College, erected on Union Hill a large building where he established his Botanico-Medical College. This building, later part of the Dale General Hospital and now Davis Hall at Worcester Academy, was built by funds subscribed by friends of the eclectic or Thomsonian system of medicine. The name of the school was changed from time to time, finally ending as Worcester Medical College. It received a charter from the Legislature in spite of strong opposition from the Massachusetts Medical Society, and for a while had a large group of students. There were six physicians and scientists on

*This study was made by me in conjunction with a paper read at a meeting of the Worcester District Medical Society in September, 1940. The figures were studied by Dr. H. L. Lombard, of the State Department of Public Health, who said "Your figures are, too low. This goes to show that public-health work pays dividends."

its faculty who gave courses of lectures of fourteen weeks, beginning each March. The tuition was \$50, with an additional fee of \$25 for an elaborate diploma. Dr. Newton died in 1853, and with him collapsed his college and its medical magazine. The Middlesex University College of Medicine now operates under this charter. Dr. Newton, at one time a member of the Worcester District Medical Society, was expelled for violation of its bylaws.

In Hersey's *History of Worcester*, published in 1862, there were listed twenty-six allopathic, four eclectic, four homeopathic, one Thomsonian and four female physicians. In 1904 Dr. Homer Gage.

civic affairs. He was for years a member of an important committee of the parent society, the Committee on Ethics and Discipline. The second was Dr. Edwin B. Harvey (1898–1900), of Westboro. He was a member of the Legislature, and during that time he was the author of the law establishing the Board of Registration in Medicine and was for many years secretary of that board. The third was Dr. George B. Francis (1902–1904), of Worcester, a Civil War surgeon. It was his steadfast demand that opened the doors of the Massachusetts Medical Society to women. The fourth was Dr. Walter P. Bowers (1912–1914) of Clinton, at one time secre-

FIGURE 6. *The Dale General Hospital.*

in his oration before the society, quoted Dr. William Osler as stating:

There are two factors in the progress of medicine, one the skeptical spirit fostered by Paris, Vienna and Boston physicians and second, and above all, the valuable lessons of homeopathy, the infinitesimals of which certainly would do no harm and quite as certainly do no good. A new school of practitioners has arisen which cares nothing for homeopathy and less for so called allopathy. It seeks to study rationally and scientifically the action of drugs, old and new.

Thus has passed into history a controversy that was vigorous while it lasted. I prophesy that at some time whatever is of merit in any of the methods of therapy not now approved by the society will eventually be accepted by the medical profession.

Worcester District Medical Society has furnished the Massachusetts Medical Society with five of its presidents. The first of these was Dr. Thomas H. Gage (1886–1888), father of the late Dr. Homer Gage. He was the author of many medical papers, one of which on typhoid fever was epoch-making. He was a prominent churchman, was on the staff of the Worcester City Hospital, and was active in

tary of the State Board of Registration in Medicine. When the *Boston Medical and Surgical Journal* was taken over by the Massachusetts Medical Society, Dr. Bowers was the first editor-in-chief. No words can express the debt that the whole profession owes to him for the magnificent job that he did. The fifth was Dr. Samuel B. Woodward (1916–1919). He is a surgeon, the author of many surgical papers and a historian *par excellence*.

The opportunity must not be missed of reminding the society of the debt that it owes those who have furthered its aspirations for a "better city and a more enlightened profession," as Daniel Waldo wrote in his will.

Mr. Waldo was the first of these. Born in Boston, he came to Worcester at the age of nineteen, lived in his father's home at Lincoln Square and died in his stately residence on Main Street, at the present site of Mechanics Hall. He was a churchman, merchant, successful business man, importer and philanthropist. Mr. Harrison Bliss (Fig. 8), another benefactor, was at one time coachman for Dr.

Oliver Fisk, the first secretary of the society. He was a merchant, railroad president, city alderman and representative in the General Court.

Dr. Charles Wilder (Fig. 9), of Leominster, at one time president of the society, fathered a movement to build a county hospital in Worcester. Dr. Leonard Wheeler, first superintendent of the Worcester City Hospital, a gynecologist and president of the Board of Trustees of Memorial Hospital, wrote a famous paper on the Waldo, Wilder and Bliss Fund. He spent many hours on the problems of the Worcester Medical Library. Dr. Donald

Delahanty, a former president and a councilor for many years, was noted for his sympathy for the underdog. No one ever called on him in vain for help.

Dr. Samuel B. Woodward is one of the few members who have occupied all the offices in the gift of the society, having served as secretary, treasurer, president and councilor, as well as president of the Massachusetts Medical Society. He has been noted for his interest in the welfare of the city, and for years was president of the Worcester County Institution for Savings, the Taxpayers

FIGURE 7. *The American Temperance House.*

Adams, a captain in the United States Army in World War I, a surgeon at the Memorial Hospital, died in the flower of his work. To Dr. Edgar A. Fisher, a retiring man with unusual surgical and organizing ability, the success of the Hahnemann Hospital is in a considerable measure due. Dr. Michael Fallon, former president of the society, was a member of the State Board of Registration in Medicine, a councilor of the Massachusetts Medical Society for many years and the author of innumerable papers on surgery. He was for many years surgeon-in-chief and president of the staff of St. Vincent Hospital, and was an outstanding Catholic layman. Dr. Homer Gage, a former president of the society, famous son of a famous father, was successful in business as well as in surgery, a rare combination. He had plans for the future of the society that have never matured. These plans, made in 1904, are our goal today. Dr. William

Association and the Society for the Prevention of Cruelty to Children.

In Worcester County a pioneer work in industrial medicine has been done. Dr. W. Irving Clark, since 1911 head of the medical service at the Norton Company, and Dr. Theodore L. Story, since 1925 medical director of the American Optical Company, have blazed new trails in the care of thousands of industrial employees. Finally, Dr. James C. McCann, president of the Blue Shield, was largely responsible for the creation of that organization.

There are many more interesting epochs a satisfactory reporting of which space does not permit. Chief among these is the story of the contribution that this district has made to the war effort, from 1812 down to the present time.

Santayana has written, "He who does not remember history has to repeat it." It is hoped that by refreshing our minds from time to time concerning the past we can not only avoid the mistakes but be stimulated to find the answer to our unsolved

medical problems. Such an organization as ours has proved to be, together with similar societies all over the country, has the future of medicine in its hands.

Such progress made under a free system proves that if we are alert to take the initiative we can direct the changes that are on the way and preserve to our country and its people the best in medical practice.

In conclusion let me enumerate some of the notable direct or indirect contributions that Worcester County has made to medicine.

Here Dorothy Dix of Worcester taught the world compassion for the insane, and here was built the first state-controlled hospital for these unfortunates. From Oxford came Clara Barton of the Red Cross and Dr. Elliott P. Joslin, with his contributions to the treatment of diabetes. It was Charlton that gave Dr. William Morton, discoverer of surgical anesthesia, to the world. In Rutland the first state hospital for tuberculosis was built.

The society has been directly responsible for many activities that have or will spread their influence over the county, state and Nation. It was among the first to raise the standards of medical education. It forced the Massachusetts Medical Society to open its doors to statewide membership

FIGURE 8 Harrison Bliss

Under its leadership, Worcester was one of the first municipalities to establish a laboratory for the diagnosis of diphtheria and tuberculosis. It organized a medical milk commission that pointed

the way to combat the terrible infant mortality during the summer months. It has overcome the menace from diphtheria. It publishes a medical

FIGURE 9 Dr. Charles W. Halder, of Leominster.

bulletin, the first of its kind in Massachusetts. Finally it established a blood bank that is supplying both civilian and army needs

I am indebted to Mr Matthew Carrigan for the illustrations

THE DIFFERENTIATION OF BRONCHIOGENIC CARCINOMA
AND PULMONARY TUBERCULOSIS

NAHUM R. PILLSBURY, M.D.,* AND JOSEPH D. WASSERSUG, M.D.†

SOUTH BRAINTREE, MASSACHUSETTS

BECAUSE of the many clinical and roentgenologic similarities of bronchiogenic carcinoma and pulmonary tuberculosis, their differentiation may present certain diagnostic difficulties. Among examination. An approximately equal number of cases were seen in the Diagnostic Clinic of the hospital, and the majority were referred for consultation with a thoracic surgeon. Since these patients

Overholt's¹ cases of primary cancer of the lung, there were 40 patients who were treated for pulmonary tuberculosis because of an originally erroneous diagnosis. Similarly, Moersch and Tinney² reported that in their series of 448 patients with proved bronchiogenic carcinoma, 13 spent several months in tuberculosis sanatoriums before the correct diagnosis was established. It was therefore believed that an analysis of cases of bronchiogenic carcinoma admitted to a tuberculosis hospital might shed additional light on this perplexing diagnostic problem.

Twelve such cases were found during the last ten years; they are summarized in Table 1. All were proved either by bronchoscopy or by post-mortem

were never admitted to the sanatorium, they are excluded from this study. Excluded, too, are all metastatic malignant growths and unconfirmed primary tumors. Two patients (Cases 4 and 11) who had both cancer and tuberculosis have been included.

Although these cases form too small a group for statistical analysis, they nevertheless bring out certain diagnostic points that are especially deserving of consideration.

Sex

All the patients were men. Although bronchiogenic carcinoma does occur in women, it is preponderantly a male disease. In Overholt's¹ series, the ratio of men to women was 3.5:1.0. At the Mayo

*Superintendent, Norfolk County Hospital.
†Assistant physician, Norfolk County Hospital.

Clinic² this disease was found to occur nearly five times as frequently in males as in females. According to King,³ 80 per cent of the cases occur in males.

Age

The patients were between forty and sixty-eight years old at the time of their admission to the sanatorium. Although the disease may occur at any age, most cases are found between the fourth and sixth decades of life. Eighty per cent of Moersch and Tinney's² patients were more than forty years of

of these symptoms may occur in almost any combination both in bronchiogenic carcinoma and in chronic infectious diseases of the lungs. Hemoptysis may or may not be present. Pain may be entirely absent, or it may be exceedingly severe if the pleura, nerves or thoracic cage is involved by extension or metastases. All the patients in this series had a productive cough, but neither the character of the cough nor the gross appearance of the sputum was distinguishable from that found in many other pulmonary disorders.

TABLE 1. Summary of Proved Cases of Bronchiogenic Carcinoma (Continued).

Case No.	X-RAY FINDINGS			DIAGNOSIS CONFIRMED		COMMENT
	INFILTRATION	ATELECTASIS	CAVITATION	BRONCHOSCOPY	AUTOPSY	
1	+	0	+	0	+	This case was diagnosed as lung abscess. Thoracotomy and thoracoplasty were performed. The patient left the hospital at his own request, and died 20 days later at another hospital.
2	0	+	0	+	0	Bronchiogenic carcinoma was suspected on admission. The patient was bronchoscoped 29 days later. Metastatic cervical lymph nodes were discovered 12 days after bronchoscopy.
3	+	0	0	0	+	The patient was too ill for bronchoscopy. There was almost constant hemorrhage.
4	+	0	+	0	+	On admission there was a metastatic nodule on the anterior abdominal wall. Two sputum specimens were positive for tuberculosis. Autopsy confirmed both tuberculosis and cancer.
5	+	0	+	0	+	Destruction of ribs was noted by x-ray 1 month after admission. Metastases were found on post-mortem examination.
6	0	+	0	+	+	Malignancy was suspected on admission. Bronchoscopy was performed 31 days later. The patient died while awaiting transfer to a cancer hospital.
7	0	+	0	+	0	A bronchogram was taken 8 days after admission. A diagnosis of carcinoma was made clinically and by x-ray. Bronchoscopy was performed 1 month after admission.
8	0	+	+	0	+	The diagnosis of bronchiogenic carcinoma was made on admission. The patient was very ill; also had bronchiectasis.
9	0	+	0	+	0	Carcinoma of the bronchus was suspected on admission. Bronchoscopy, 21 days later, showed carcinoma in the right main-stem bronchus.
10	0	0	+	+	0	The patient was admitted for observation. Bronchoscopy was performed 1 month later. Infiltration of the trachea was seen, and mediastinal metastases were suspected.
11	+	0	+	0	+	The patient had tuberculosis of the right hand. Both pulmonary tuberculosis and bronchiogenic carcinoma were found at autopsy.
12	0	+	0	+	0	The patient was admitted for observation. Bronchoscopy, 1 day after admission, disclosed bronchiogenic carcinoma, with probable metastases.

age, and the highest incidence of the disease was in the sixth decade. The average age of Overholt's patients was fifty-five years.

Side Affected

In 9 of these 12 cases the disease was in the right bronchial tree. According to Betts,⁴ 31 of his 46 patients with so-called "central tumors" had right-sided involvement. Moersch and Tinney² found the disease twice as often on the right side as on the left.

Symptoms

Bronchiogenic carcinoma presents no characteristic syndrome. This point cannot be overemphasized. Of the complaints most frequently elicited — cough, expectoration, hemorrhage and pain — all or any

The absence of pathognomonic symptoms in carcinoma of the lung has been stressed by Fetter,⁵ Overholt¹ and others. Of the group of cases reported by Moersch and Tinney,² 5 per cent had, indeed, no symptoms referable to the thorax.

Signs

The physical findings in the thoracic examination depend primarily on the size and situation of the tumor. The signs are therefore exceedingly variable, and this point has also been stressed by other writers. In the present series, dullness of some degree and alterations in breath sounds were noted in every case. Rales, often apical, were detected in 8 cases.

X-Ray Diagnosis

The x-ray diagnosis of bronchiogenic carcinoma has recently been discussed in detail by Holmes⁶ and Scatchard.⁷ Overholt¹ has also included in his paper excellent reproductions of roentgenograms that illustrate how closely this disease may simulate pulmonary tuberculosis. Any combination of the roentgenologic findings characterized as infiltration, atelectasis or cavitation may be present. Half the cases in the present series had cavitation on their admission x-ray films.

In regard to x-ray diagnosis, Moersch and Tinney² wisely point out, "It is also important to remember that a negative roentgenogram does not definitely rule out the presence of carcinoma." If symptoms are suggestive and persistent, a negative roentgenogram should not deter one from further diagnostic studies.

Bronchoscopy

Betts,⁴ in a thorough discussion of the subject, has called bronchoscopy "the most important method of diagnosis in primary carcinoma of the lung." To be of value from a therapeutic standpoint, however, bronchoscopy must be performed early in the course of the disease. Usually the progress of bronchiogenic carcinoma is rapid, its duration being measured in months. The delay between the time the disease is first suspected and the time of bronchoscopy—or some other definitive diagnostic study—should be counted in days, not in weeks or months.

In half these cases the diagnosis was made by bronchoscopy, and the interval from admission to bronchoscopy varied from one day to one month. Two patients (Cases 3 and 8) were too ill for bronchoscopic examination; two other (Cases 4 and 5) had evident metastases. In 1 case (Case 1), seen in 1934 and not bronchoscoped, the diagnosis was missed clinically and made only at post-mortem examination.

DISCUSSION

Patients with bronchiogenic carcinoma are occasionally admitted to a sanatorium either for observation for tuberculosis or because a definite diagnosis of tuberculosis has already been made. This is not surprising since, clinically, lung cancer may closely resemble tuberculosis. For this reason reliance must be placed on other diagnostic aids, such

as x-ray examination, bronchoscopy and exploratory thoracotomy. Since the x-ray film itself may also be misleading, bronchoscopic examination is of the utmost importance.

Bronchiogenic carcinoma must be promptly differentiated from tuberculosis, since time and rest never cure a malignant growth. Waiting six weeks or longer for results of animal inoculation tests or cultures of sputum may rob the patient of his chance of surgical cure.

An early diagnosis of bronchiogenic carcinoma can be made only if the disease is suspected and considered in the differential diagnosis. The possibility of cancer must be given special consideration if the patient is a man between forty and sixty years of age. In all cases in which thoracic symptoms are present, x-ray examination of the chest should be made immediately. If, on the basis of physical and x-ray examination, the disease cannot be differentiated from pulmonary tuberculosis and a few specimens of sputum are negative, bronchoscopy should be performed without further delay. Inspection of the bronchi, if the patient's general condition admits it, yields valuable information that may determine not only the diagnosis but also how the case is to be managed. This is as true of pulmonary tuberculosis as it is of bronchiogenic carcinoma, since the presence or absence of endobronchial tuberculosis may alter plans for collapse therapy. Hence, in either disease much may be gained by prompt bronchoscopic examination.

SUMMARY

Twelve proved cases of patients with bronchiogenic carcinoma who were admitted to a tuberculosis hospital are presented. The clinical and roentgenologic similarities between carcinoma and tuberculosis of the lung are pointed out, and the diagnostic role of bronchoscopy is emphasized.

CLINICAL NOTE

THERMAL BURNS IN DIABETES MELLITUS*

HOWARD F. ROOT, M.D.†

BOSTON

THE recent report of Taylor, Levenson and Adams¹ emphasizes the marked hyperglycemia found in nondiabetic patients suffering severe thermal burns that involve 2 to 75 per cent of the body surface. Death occurred in 14 of their 35 cases. It is instructive to compare the metabolic changes when serious burns occur in diabetic patients in whom there is a known deficiency in insulin. For this reason, the following cases are reported to illustrate the effects of burns from hot water and from the sun's rays.

CASE 1 (4541). A 66-year-old housewife had diabetes of 7 years' duration. A leg had been amputated for gangrene on February 12, 1925, and the other leg on August 29, 1930. Although insulin had been used for a brief period at the times of operation, the diabetes was of the typically mild degree often associated with gangrene. She had therefore not regularly taken insulin, and the urine was sugar-free with diet alone. The fasting blood-sugar level had varied from 110 mg. to 210 mg. per 100 cc.

On June 11, 1931, while the patient was sitting in a wheel chair washing dishes, boiling water was spilled on her arm and back. Vomiting followed for 3 days. On June 15, she entered the Deaconess Hospital with a second-degree burn on the right arm and a large eschar on the left buttock, the site of the worst burn. She was prostrated, and although not unconscious was in severe acidosis. The blood-sugar level was 480 mg. per 100 cc., and the nonprotein nitrogen 47 mg. The carbon dioxide combining power of the venous blood was 19 vol. per cent, and rose to 27 vol. in 10 hours with 55 units of insulin.

The patient received 195 units of insulin in the first 2 days. On the 10th day, the blood-sugar level was 80 mg., and the nonprotein nitrogen 33 mg., and only 50 units of insulin was required. The urine still showed much albumin. The patient was at times irrational. At first the burns showed no evidence of serious sepsis but this later developed and she died on the 19th day.

CASE 2 (3376). A 55-year-old clerk had diabetes of 15 years' duration when he returned in 1938 for a second period of observation. In 1923 his diabetes was so mild that he required only dietary treatment for the urine to be sugar-free.

In May, 1937, he had a severe sunburn on the shoulders and back; the skin became infected, with the formation of multiple carbuncles. Presumably as a result of bacteremia, he developed phlebitis and osteomyelitis of the right leg, which necessitated a mid-thigh amputation in December, 1937. In this same month, prostatic and paranephric ab-

scesses were found, and the paranephric abscess was drained in January, 1938.

On admission to the New England Deaconess Hospital on March 3, 1938, an inguinal abscess was present, which was drained. The patient still had marked pyuria. The white-cell count was 30,000. The urine contained 1.8 per cent sugar, and the fasting blood sugar was 150 mg. per 100 cc. He was given daily doses of 10 units of crystalline and 40 units of protamine zinc insulin. Recovery was uneventful, and with the exception of a recurring abscess in the inguinal region in September, 1938, from which recovery occurred, he has done reasonably well following a diabetic diet and taking insulin as indicated.

Comment. The instructive feature in his case is the fact that during the period when he suffered severe sunburn and carbuncles developed, his diet was not weighed or measured and the urine was not sugar-free. The failure to control the diabetes may well have been an important factor encouraging the spread of infection, which ultimately led to an amputation of the leg, paranephric abscess and prostatic abscess.

Among the factors contributing to the increased blood sugar in the nondiabetic patients of Taylor, Levenson and Adams, increased glycogenolysis in the liver was mentioned. Another possible source of the extra blood sugar was considered to be gluconeogenesis from protein, since it has been shown that after thermal burns there is an early increase in protein metabolism. It is possible to add one other factor in discussing the causes of the change in the blood-sugar level, namely, the part played by the skin itself.² The skin normally contains much glycogen and some glucose. In diabetic patients with poor control, the normal glycogen stores are greatly reduced but the glucose is increased. This is also true with severe infections involving diabetic patients. When the blood-sugar level is high, it is possible for as much as 20 or 25 gm. of glucose to be present in the skin, and therefore if large areas of the skin are injured, liberation of glucose from the skin may contribute a material increase in blood sugar. In the cases of Taylor, Levenson and Adams, the administration of 25 gm. of glucose intramuscularly was followed by evidence of its utilization within two hours. In nondiabetic patients endogenous insulin is available, but in diabetic patients the lack of normal insulin reserve might result in quite different changes in the blood and tissue chemistry.

MEDICAL PROGRESS

HEMATOLOGY (Concluded)

WILLIAM DAMESHEK, M.D.*

BOSTON

ANEMIA DUE TO BONE-MARROW DISTURBANCES

Anemia due to a disturbance in the bone marrow is usually normochromic (normal color index) and normocytic (normal cell volume and normal cell diameter) because what red cells are produced by the more or less incapacitated marrow are normal from the standpoints of hemoglobin content and cell size. Leukopenia and thrombocytopenia are usually associated phenomena; in other words, there is a *pancytopenia*.

The presence of pancytopenia — anemia, leukopenia, granulocytopenia and thrombocytopenia — should at once lead to the suspicion that a condition involving the bone marrow is present. In general, the diagnostic possibilities are as follows: hypoplasia or aplasia of the marrow, as a rule due to chemicals, at times of idiopathic nature and occasionally associated with myxedema or nephritis; replacement of the marrow by abnormal cells, as in leukemia, lymphosarcoma, reticulosis, Gaucher's disease and fibrosis; so-called "maturation arrest," as seen in liver-extract deficiency; and diminished delivery, usually due to hypersplenism. In the last, although the marrow is normal, in fact hypercellular, the peripheral blood contains fewer red cells, white cells, and platelets than normal. Many of these cases are associated with outspoken splenomegaly. In some, the spleen, although not enlarged, is hyperactive and thus results in an undue inhibitory effect on the bone marrow. This indicates a hormonal relation between the spleen and the bone marrow.

These cases — except those due to pernicious anemia — are almost always refractory to therapy with liver extract, iron and so forth. Bomford and Rhoads¹⁸ have for this reason grouped them all together in the single designation "refractory anemia," hardly a scientific term for such diverse bone-marrow pictures. My own feeling is that a serious attempt should be made in these cases to establish, so far as possible, an etiologic or at least a pathologic diagnosis. Chronic nephritis and myxedema should be ruled out by appropriate measures. The question of a more or less occult hemolytic process should be gone into by studies of the blood bilirubin, of the output of bile pigments, particularly in the feces, and of the reticulocyte level. But the central point in diagnosis is the sternal-marrow biopsy. A preliminary puncture is performed. If good flecks of marrow are obtained, giving a clear-cut picture in the stained smears, no further testing

of the marrow is required. If, however, the material aspirated is minimal in amount and contains few marrow cells, a trephine biopsy should be carried out. It is by no means necessary to remove — as is so often done — a large section of sternum through a 5-cm. or 7-cm. incision. An incision 1 or 2 cm. in length is entirely satisfactory with the use of a trephine with a head 5 to 7 mm. in diameter.

A series of excellent articles on the subject — even though the condition is, unfortunately, referred to as "refractory anemia" — is that by Davidson, Davis and Innes.¹⁹ These studies are characterized by careful marrow examinations and by classification of the various cases as anemias with hypocellular, normoblastic marrows, those with cellular marrows and so forth. In the group characterized by hypocellular, normoblastic sternal marrows, 4 were secondary to chemical exposure but the remaining 12 were idiopathic. Of these 16 cases, 9 were progressive and fatal within the period of a few months. In the cases with a hypercellular megaloblastic marrow, the response to the persistent use of liver extract, although slow, was nevertheless satisfactory, and for this reason, one must seriously consider that these cases were examples of the relatively refractory type of pernicious anemia that Israëls and Wilkinson⁶ have called "achrestic anemia." To put these cases under the nondescript term "refractory anemia" makes the whole thing rather confusing and again illustrates the value of classifying a given case of anemia on the basis of cell size, and of probable etiologic mechanisms. In a more recent paper, Davis and Davidson²¹ point to the value of the oral administration of proteolyzed liver in a number of cases of rather atypically refractory pernicious anemia in which injections of liver extract had proved ineffective. One wonders in these cases whether the injectable liver extract was really of a high degree of potency.

Of 89 personally studied cases showing pancytopenia,²¹ the largest group — 28 cases, or 31.4 per cent — was made up of examples of aleukemic leukemia. In these, the marrow showed an extreme degree of leukocytic hyperplasia, with the presence of many primitive leukocytes, either of the lymphoid, myeloid or monocytic variety. Thirteen cases were in a closely related category, that is, Hodgkin's disease, lymphosarcoma or multiple myeloma (plasmacytoma). Thus in 89 cases with pancytopenia, the fundamental cause of this symptom complex in almost half the cases was a proliferative disease of one of the three white cell-forming

*Professor of clinical medicine, Tufts College Medical School; visiting physician and hematologist, New England Medical Center.

tissues. Pancytopenia is thus an ominous portent of these grave disorders.

Widespread fibrosis of the marrow may occur either secondarily to such conditions as leukemia, lymphosarcoma and metastatic carcinoma or, more frequently, following protracted polycythemia vera. At times it is associated with marble bone or Albers-Schönberg disease and may then be called "osteopetrosis." Rosenthal and Erf²² describe 1 such case, together with 17 cases of myelofibrosis secondary to various causes. These cases, which have been described under a veritable welter of names, including leukoerythroblastic anemia, osteosclerotic leukemia, nonleukemic myelosis, leukanemia and agnogenic myeloid metaplasia, have as their distinguishing features the following: anemia and well-marked splenomegaly; bone changes consisting of irregular osteoporosis and osteosclerosis, principally in the femurs; anemia, leukocytosis or leukopenia and thrombopenia; and nucleated red cells and myelocytes, which are present in fair to considerable numbers. The presence of these early red and white cells in association with a progressive anemia bespeaks either an unusually vigorous attempt at blood formation or a rather bizarre and uninhibited type of nonproductive hematopoiesis. This is probably associated with the concomitant myeloid metaplasia of the spleen, which occurs secondarily to the initial bone-marrow fibrosis. Blood formation in the spleen is not an unnatural condition, since it probably represents a reversion to embryonic hematopoiesis; nevertheless, it lacks the normal regulatory influence that the spleen itself usually exerts on the bone marrow. This gives rise to an abnormal type of blood picture, characterized by an excess of normoblasts and myelocytes.

These cases are often difficult if not impossible to differentiate from those of chronic myelogenous leukemia with a subleukemic picture, that is, one in which the leukocyte count falls between 8000 and 20,000. In fact, some of the cases that Jackson, Parker and Lemon²³ have called "agnogenic myeloid metaplasia," that is, myeloid metaplasia arising *sui generis*, may in reality be examples of chronic myelogenous leukemia. That fibrosis of marrow may occur in chronic leukemia has been shown in a careful study by Churg and Wachstein,²⁴ who, in 97 cases of myeloid leukemia, found 6 showing myelofibrosis. Osteosclerosis is only rarely, if at all, associated with true leukemia. I have recently, however, seen a case that fulfilled all the criteria of myeloid metaplasia of the spleen secondary to myelofibrosis, and with the extensive bone changes of osteosclerosis, in which there were a striking regression in the size of the spleen and a striking improvement in the hemoglobin and erythrocyte values following x-radiation over the spleen. X-ray therapy and splenectomy have been said to be contraindicated because the spleen might be the only available source of hematopoiesis. A trial of

x-ray therapy in relatively small doses directed over the spleen seems to be indicated in doubtful cases.

In cases showing pancytopenia and a large spleen, and in which the marrow shows erythroblastic hyperplasia without evidence of leukemia, particularly if some evidences of increased hemolysis are present, one should at least consider the possibility of hypersplenism. Splenectomy in some of these cases has been dramatically successful, not only in raising the red-cell count to normal but also in bringing the low leukocyte and platelet counts to normal values. These cases are closely related to the syndromes of "splenic neutropenia,"²⁵ acquired hemolytic anemia and idiopathic thrombopenic purpura. The incidence of these cases should materially increase as their possibility is more frequently considered.

ANEMIAS DUE TO EXCESSIVE LOSS OF BLOOD

Hemorrhagic Anemia

Many cases treated routinely for months or even years with liver extract, iron and vitamin B complex are found — often too late — to be examples of chronic hemorrhagic anemia, usually secondary to bleeding from the gastrointestinal tract. With a little attention to a few morphologic details in the blood and with more frequent examinations of the stools for occult blood, these cases could doubtless be diagnosed more frequently.

Although the anemia in these cases is usually hypochromic, with color indices in the vicinity of 0.5, I have seen occasional cases with normochromic anemia, particularly when the bleeding was brisk. The white-cell count is usually low (4000 to 6000), but the granulocytes are usually slightly elevated. Stippling may be present. The platelets are usually moderately or greatly increased. The hypochromic anemia indicates a hemoglobin deficiency for the normally developing normoblasts; in association with reticulocytosis and increased platelets, indicating a hyperactive bone marrow, there is a definite likelihood of chronic hemorrhage.

Careful search for cause of the anemia should be instituted. Stool examinations for occult blood and exceedingly careful x-ray examination of the gastrointestinal tract are in order. Possibilities are diaphragmatic hernia, bleeding peptic ulcer, carcinoma of the stomach, carcinoma of the cecum or colon, Meckel's diverticulum, terminal ileitis with hemorrhage and even the lowly hemorrhoid. Lesions of the small bowel are often missed in hurried x-ray examinations, and for this reason, careful fluoroscopy with the spot film technic is invaluable.

Hemolytic Syndromes

Mechanisms. Little is known of the mechanisms of normal blood destruction. The mature non-nucleated red cell, after many trips about the

circulation, probably wears out and is then converted into a denatured protein, bilirubin and iron. Is the spleen truly the graveyard of the normal red cell or does it simply cause the red cells to swell as they stagnate there for variable periods? Do agents of various types — the lysolecithin of Bergenhem and Fahreus, immune hemolysins or agglutinins and various metabolic products — bring about gradual hemolysis? There is at present no answer to these questions.

Since 1940, Johnson and Freeman²⁶ have been concerned with the hemolytic action of chyle and its possible relation to normal blood destruction. After a fat meal, they state that the circulating red cells become exposed to a sufficiently high concentration of hemolytic material to cause an increase in blood destruction. This was demonstrated by exposing normal red cells to normal and lipemic serums and by observing the degree of hemolysis in both. Lipemic serums, which were obtained from persons who had taken a large amount of cream or corn oil, were slightly, although distinctly, hemolytic. Normally, however, the red cell is protected from an undue concentration of lipemic plasma by several mechanisms, including chiefly the high dilution of the hemolytic chyle that occurs with the large volume of blood in the subclavian vein and heart. Although this mechanism, as postulated by Freeman and Johnson, may well be one factor, a likelier one is probably the purely mechanical action involved in the squeezing and buffeting about which the red cell develops within the capillaries. This factor of mechanical fragility, which was investigated by Miller and myself²⁷ a few years ago, has more recently been studied by Shen, Castle and Fleming.²⁸ When normal red cells are shaken in a test tube or other container with glass beads for a given length of time, for example, three hours, a small amount of hemolysis takes place, which varies from 1 to 3 per cent. The mechanical fragility is greatly increased in the presence of an agglutinating agent (see below), which presumably still further injures the rather tough red-cell membrane. One must concede that the mechanisms of normal hemolysis are but little known and must await further elucidation.

In the field of abnormal or increased hemolysis, a number of different mechanisms may operate to destroy the red cell. One may list these as follows: bacterial agents, notably the hemolytic streptococcus; parasites, notably that of malaria and the bartonella of Oroya fever; chemicals, including the sulfonamide drugs and phenylhydrazine; immune hemolysins; agglutinins, cold and warm, usually of the immune-body type; certain physical factors, such as extreme heat and cold; unknown factors; and hypersplenism.

Bacterial agents, parasites and chemicals appear to attack the red cell directly. Hemolysins, as Dameshek and Miller²⁷ have shown, may be simple

or complex. The simple ones hemolyze the red cell directly, whereas those which are complex require the mediation of complement. Thus, with the immune hemolysin that occurs in certain cases of acute hemolytic anemia, the amboceptor has a sensitizing or agglutinating or membrane-injuring role, whereas actual hemolysis is brought about by complement. In other types of hemolytic anemia, the presence of a hemolysin may be noticeable only by the behavior of the red cell. Thus, the small, thick red cell, the spherocyte, which is fragile in hypotonic solutions of sodium chlorides, has probably been already injured by a hemolysin that cannot be detected by any means at present at one's command. The red cell of chronic hemolytic anemia with paroxysmal nocturnal hemoglobinuria, which is abnormally fragile to dilute acid and also to heat, is probably abnormal because it has been acted on by a hemolysin, which itself cannot be detected. In paroxysmal cold hemoglobinuria, a well-defined hemolysin can be demonstrated, as first described many years ago by Donath and Landsteiner. This hemolysin requires so-called "sensitization" with cold, then warmth and finally the presence of complement. The chemical nature of hemolysins is almost a completely untouched field.

Agglutinins, by causing red cells to mass together, probably injure the red-cell membrane, as can be readily shown by exposing a red-cell suspension to varying concentrations of agglutinin and then shaking them in a mechanical shaker. The effect of shaking on agglutinated red cells is probably similar to the buffeting that these cells receive in a highly active circulation. In any event, the mechanical fragility of agglutinated red cells is greatly increased over normal (up to 80 per cent in a three-hour period). This is evident in transfusion reactions associated with incompatible blood. The extreme hemolysis, with hemoglobinuria and acute hemolytic anemia, that ensues is due to agglutination, with its injurious effect on the red-cell membranes, and the mechanical activity of an actively moving circulation. This type of agglutinative-hemolytic reaction is also seen in acute hemolytic anemia of the newborn (erythroblastosis fetalis) and in certain cases associated with the presence in the blood of an unusually high concentration of cold hemagglutinins.

The red cell may also be injured by a variety of physical agents, including heat, cold and various light rays. Undue heat, as in a thermal burn, by directly injuring the red cells in superficial capillaries may bring about their quick rupture and thus cause hemoglobinuria or their slower degradation by way of the spherocyte. This is another link in the concept that the spherocyte is a red cell that has been injured by some type of hemolytic agent and has therefore assumed an abnormal, unusually spherical form. This renders the cell unusually vulnerable to hemolysis by either splenic or other mechanisms.

Hypersplenism, in which an undue or abnormal activity of the spleen is postulated, is becoming increasingly evident as a cause of hemolytic anemia. The enlarged spleen of many conditions — portal hypertension, splenic-vein thrombosis, Hodgkin's disease and certain other conditions — may somehow develop an unusual degree of hemolytic activity. These cases are usually accompanied by leukopenia and thrombopenia, both of which are probably due to hypersplenic inhibition, rather than to unusual phagocytosis by splenic cells.

There are probably many other factors that injure the red cells and result in various degrees and types of hemolytic anemia. Hereditary factors involving hemoglobin metabolism and the structure of the red cell, as in Mediterranean target-oval-cell syndromes and in sickle-cell disease, and obscure factors, such as the hemolytic anemia symptomatic of Hodgkin's disease, Boeck's sarcoid and dermoid cyst, are among these totally unknown causes of increased blood destruction. A consideration of the etiologic factors may be distinctly worth while in working out the possible mechanism in a given case of hemolytic anemia and in making the ultimate decision regarding the value of splenectomy as a therapeutic procedure.

Differential red-cell fragility. Red-cell fragility has for many years been associated with the reaction of red cells to hypotonic salt solutions. This test serves only to discriminate between cells showing varying degrees of thickness, the range of hemolysis in a given case indicating the limits of the "thickness population" of the red cells. Normally, some begin to hemolyze in a 0.45 per cent solution of sodium chloride but all become hemolyzed at a 0.25 per cent concentration. Thick red cells — spherocytes — begin to hemolyze at concentrations close to that of normal saline solution, and thin red cells — leptocytes or target cells — are at times incompletely hemolyzed even in solutions containing as little as 0.04 per cent of sodium chloride. An amusing, although sound, article from Honolulu on erythrocyte fragility is that by Fennel,²⁹ who recommends a simple one-tube "screen test" for determining whether or not abnormal hypotonic fragility is present. A 0.38 per cent solution of sodium chloride is employed, and the degree of hemolysis is measured with the photoelectric colorimeter. If any increase in the normal degree of hemolysis is present, a second or serial dilution test is carried out. The author concludes, "At least, try the one tube of 0.38 per cent saline in conjunction with your routine hematology, and see if you don't get interested."

One should always realize that whatever a red cell shows in its reaction to hypotonicity does not necessarily indicate its reaction within the circulation, where everything is always isotonic. There may, then, be other ways of measuring red-cell vulnerability or fragility.

The question of acid hemolysis or fragility has already been mentioned. In one disease, and apparently in only one, as Ham³⁰ and others have pointed out, the red cell is unusually vulnerable to dilute acids. A presumptive test may be made with carbon dioxide gas, and the complete test with various types of dilute acids, with and without complement.

The matter of mechanical fragility has also been alluded to. It may be worth while to introduce this method as a more or less routine measure in the study of hemolytic anemias. Mechanical fragility is increased in the presence of warm and cold hemagglutinins (when testing for the latter, the serum must be kept cold) and to some extent in such conditions as sickle-cell and other hemolytic anemias.

Heat fragility has recently been introduced by Hegglin and Maier.³¹ This is a simple test in which a tube of clotted blood is placed in an incubator at 37°C. for three to twenty-four hours. Apparently in only one disease, again paroxysmal nocturnal hemoglobinuria, are sufficient red cells hemolyzed with simple incubation to result in hemolysis readily visible to the naked eye. The precaution must be used of taking the blood with a dry syringe and under as little stasis as possible.

One may thus study the resistance of the red cells in a given case of hemolytic disease by at least these four methods and arrive at a more or less etiologic diagnosis. Doubtless, other methods may be used, as Dameshek and Singer³² suggested some years ago, including resistance to saponin, lecithin, lysolecithin and so forth. The concept of differential fragility serves to indicate that when the red cell is injured by different substances it reacts differently.

Clinical features. As pointed out in previous reviews, three types of *hereditary hemolytic syndromes* may be discriminated: familial spherocytosis (congenital or familial hemolytic anemia or jaundice); Mediterranean target-oval-cell disease (Cooley's anemia, thalassemia, Mediterranean anemia or familial leptocytosis); and sickle-cell anemia. Of these, familial spherocytosis is by far the best known. Mediterranean target-oval-cell disease has been known for some years as a severe, fatal condition. The milder types have only recently been studied (Wintrobe et al.,²² Dameshek²⁴ and Smith²⁶). These observers have all pointed out the numerous gradations in the types of cases — from the most fatal form, Cooley's anemia, down to the extremely mild cases, in which abnormalities can be demonstrated only by careful hematologic studies. The severest cases show marked anemia, increased hemolysis, splenomegaly, significant bone changes and the presence of numerous nucleated red cells in the circulating blood. Moderately severe cases present moderate anemia, splenomegaly, slight icterus and minimal bone changes. Mild cases show absolutely nothing on physical examination and only slight

hypochromic anemia or erythrocytosis in the blood counts. All types, severe, moderate and mild, show target and oval red cells in varying concentrations and increased resistance of the red cells to hypotonic salt solutions. The red cells are unusually thin, apparently because of a disturbance in hemoglobin synthesis, with the formation of normal-sized cells lacking sufficient hemoglobin for the amount of cytoplasm that is present. Iron therapy is totally ineffective, and hemoglobin values remain surprisingly constant.

These cases are apparently transmitted by a Mendelian dominant mechanism. A careful study of them from the standpoint of the morphology of the blood was made by Valentine and Neel.³⁶ The mild cases are apparently transmitted by a heterozygous gene, but the severe cases are transmitted through two parents, both bearing this gene. This confirms my own studies,³⁴ which showed that both parents of patients with severe cases (Cooley's anemia) showed mild target-oval-cell abnormalities. Valentine and Neel point out that this is one of the few diseases in which carriers can be discriminated by careful laboratory studies. These syndromes deserve increasing attention, since they are undoubtedly frequent among Italians and not infrequent among Greeks, Syrians and Portuguese. Anemia, jaundice, splenomegaly, peculiar bone changes and stippling of the red cells occurring in one of these racial groups should always make one consider the possibility of a target-oval-cell syndrome.

More attention is also being paid to sickle-cell disease, which in many respects resembles target-oval-cell disease rather strikingly, and may in fact be related to it. In sickle-cell disease, as in the Mediterranean syndromes, a central feature is the presence of thin, hypotonically resistant, target cells. Hemolysis and splenomegaly are features of the severe cases, and there is no response to the administration of iron, despite the hypochromic character of the anemia. The carriers of the disease may well be those with the sickling trait, who number about 7 per cent of the Negroes in this country. Sickle-cell disease, although almost exclusively limited to those of African origin (colored), also occurs to some extent in Italians and occasionally in Portuguese — apparently without any colored admixture. The highly abnormal sickled cell may be related to the elongated, elliptical cell of the Mediterranean disease.

An interesting study of the occurrence of sickleemia in the black Carib Indian had been made by McGavack and German.³⁷ The black Caribs are not truly Indians but natives of Honduras who have preserved for centuries the purity of their original racial African stock. Twenty-four (8 per cent) of the 300 persons studied showed the sickling phenomenon. None had apparently had sickle-cell

disease, and sickle-cell anemia as such had never been recorded in the local hospital.

Murphy and Shapiro³⁸ describe a new technic for demonstrating the sickling trait. By this method the process of sickling can be readily studied from the stage of the normal flexible red cell to the stage of sickling when flexibility is lost and the cell appears "as fixed and rigid as a crystal of ice as it moves about and abuts against cells and fixed objects." These and other observations led Murphy and Shapiro to conclude that the dissociation of combined hemoglobin bears a causal relation to the phenomenon of sickling. Because of its rigidity within the circulation, the sickled cell may be unusually vulnerable to mechanical trauma (mechanical fragility).

Winsor and Burch³⁹ showed that the sedimentation rate in sickle-cell anemia may be used as a diagnostic measure. By oxygenating sickle-cell blood the sedimentation rate increases, and by adding carbon dioxide to the blood the rate decreases. Instead of adding carbon dioxide to the blood, one may study the sedimentation rate of blood taken with and without stasis by means of a tourniquet applied for six minutes. The lability of the sedimentation rate with respect to oxygen and carbon dioxide and the relation of the different rates to each other are said by the authors to comprise a "diagnostic parameter." If the difference between the two sedimentation rates is greater than 20 mm. per hour, the patient has sickle-cell anemia.

Bauer and Fisher⁴⁰ describe a nonanemic variety of sickle-cell disease. All Negro patients should be routinely tested for sickleemia to avoid such erroneous diagnoses as rheumatic fever, rheumatic heart disease, polyarthritis and cerebral disease. The authors report 6 cases in which the pathologist diagnosed the condition post mortem; in 5 of these the clinician had not even suspected the condition. Brugsch and Gill⁴¹ report 4 cases of sickle-cell anemia in which the diagnosis was obscured by the presence of polyarthritis and heart murmurs simulating rheumatic fever. Italians, too, may have symptoms simulating various conditions but which in reality are due to sickle-cell disease. Thus Canby, Carpenter and Ellmore⁴² report a case in which an apparently acute surgical condition of the abdomen in a youth of pure Sicilian stock was due to multiple infarctions of the spleen. Splenectomy was performed, and later sickle-cell anemia was discovered. Reinhard, Moore, Dubach and Wade⁴³ describe the results of a careful study of the effects of high concentrations of inspired oxygen in patients with sickle-cell anemia. Although a decrease in the degree of intravascular sickling of the red cells occurred, there was no consistent detectable change in the rate of hemolysis. In fact, erythrocytogenesis was depressed by the oxygen therapy, both the reticulocytes and the red cells being decreased; when

oxygen was discontinued, a striking increase in reticulocytes occurred.

A good review article on the *acquired hemolytic syndromes* is that by Davis.⁴⁴ Acute hemolytic anemia following the administration of sulfadiazine is often accompanied by the presence in the blood serum of a cold hemagglutinin. This has been commented on, among others, by Layne and Schem⁴⁵ and by myself.⁴⁶ The exact relation of the cold hemagglutinin to the drug and to the hemolytic anemia is obscure. Its presence in high titer may lead to a false interpretation of "incompatibility" in testing the patient's serum with prospective donor's red cells prior to transfusion. This may readily be obviated by performing the cross-match according to Landsteiner's test-tube method at incubator temperature. The blood should be warm when administered; if bank blood is used, it should be allowed to warm at room temperature for two or three hours. Stats⁴⁷ studied 2 cases in which extremely high titers of cold hemagglutinin were present, demonstrating the importance of mechanical trauma as a cause of hemolysis in agglutinated red cells. This is in line with the previous work of Dameshek and Miller²⁷ showing the injurious effect of agglutinin on the red-cell membrane and the importance of mechanical trauma as a cause of hemolysis whenever a hemagglutinin in sufficiently high titer is present. This is presumably true not only in patients with a cold hemagglutinin but also in transfusion accidents due to incorrect cross-matching and to the presence of an anti-Rh agglutinin (Rh-factor reaction). The red cells are injured when they become agglutinated, and being present in agglutinated masses, they are vulnerable to the constant buffeting about in an active circulation. Intravascular hemolysis then takes place, with resultant hemoglobinemia and hemoglobinuria. Masses of acid hematin are usually precipitated in the renal tubules, and nephropathy follows. A case of chronic hemolytic anemia with autoagglutination and hyperglobulinemia is reported by Kracke and Hoffman.⁴⁸ A similar case was recently studied by Katz and myself.⁴⁹ Hyperglobulinemia was also present and was presumably due to the exceedingly high titer of cold hemagglutinin, which was 1:500,000. Intravascular agglutination could be readily demonstrated by microscopic examination of the capillaries at the nail bed and in the cornea. Hemoglobinemia occurred when a whole arm was immersed in iced water.

Acute hemolytic anemia of the newborn (erythroblastosis fetalis) has now been firmly established as due to a reaction between the Rh antibody (anti-Rh agglutinin) and the Rh factor or agglutigen Levine,⁵⁰ whose pioneer work in this field is outstanding, presents a review of the pathogenesis of the disease. In this paper, the technics of agglutination tests and their interpretation, the varieties of human anti-Rh serum, the matter of the so-called

"Hr factor" as it occurs in mothers who are Rh+, familial and racial factors and the treatment with transfusions of Rh- blood are discussed. This article will repay careful reading. Another excellent and comprehensive review is that by Potter.⁵¹ Comments concerning the laboratory problems involved in Rh-factor testing are presented by Kracke and Platt.⁵² These are often difficult. The clinician reading a report of "Rh-" or "Rh+" rarely knows the difficulties that are often encountered in the laboratory in making the decision. Too many weak serums are on the market that give false negative reactions. Until a good animal or other method is developed for preparing anti-Rh serum, these difficulties will doubtless continue. The other big problem is the possibility of developing some method for neutralizing the mother's anti-Rh agglutinin so that it cannot agglutinate the fetus's Rh+ red cells. Until this comes about, the erythroblastotic-producing mother is faced with the constant and recurring threat, with each new pregnancy, of the development in the fetus of hydramnios, acute hemolytic anemia, severe jaundice and so forth.

The *idiopathic hemolytic anemias*, unassociated with agglutinins or reactions to drugs, are of great interest. I have recently seen an increasing number in which the spleen seemed to be the central feature of the disease and the resulting hypersplenism the cause of the hemolytic anemia, the leukopenia and the thrombopenia. The mechanisms by which the spleen in these cases gives rise to increased hemolysis are quite obscure. The leukopenia and thrombopenia may be explainable by an unusual degree of inhibition of the bone marrow by an overactive spleen. Splenectomy is usually — not always — followed by a dramatic rise in the red-cell count to a normal or increased value. I⁵³ have discussed the physiologic pathology and the therapy of these cases in a recent article.

CASE 31101

PRESENTATION OF CASE

First admission. A fifty-four-year-old practical nurse was admitted to the hospital because of progressive muscular weakness and a skin eruption.

Five months prior to admission the patient began to feel weak, fatigued easily and perspired excessively. Her symptoms progressively increased. About two months before entry, she developed an erythematous rash on the back of the neck and around the fingernails. This gradually involved the forehead, the perinasal regions, the ears and chin, the arms and the dorsal aspects of both hands. It was associated with slight itching, and there was deep tenderness on pressure over these areas. There was no history of exposure to drugs or chemicals,

*On leave of absence.

nor had there been any recent exposure to sunlight. About five weeks before entry she developed gradually increasing edema of both eyelids and exhaustion became so marked that she was forced to stop working. In the month before admission muscular weakness increased to the point where the act of combing the hair on dressing herself required considerable effort. Pain and stiffness at the base of the neck prevented her from holding the head erect. A sensation of a lump in the throat made swallowing difficult. Her weight fell from about 200 to 180 pounds.

The patient gave a history of intolerance for highly spiced and fried foods for many years. About ten to twelve years previously she had had severe attacks of indigestion and excruciating pain in the right upper quadrant radiating through to the back. These attacks lasted several hours and were associated with vomiting of bitter material. There was no history of jaundice or of clay-colored stools. Two months before admission she was found to have a repeatedly positive Wassermann reaction, for which she had received two injections of Mapharsen.

The patient's mother and two half uncles died of tuberculosis. One of her daughters also had tuberculosis. Her husband had a positive Wassermann reaction.

Physical examination revealed a well-developed and well-nourished woman who appeared acutely ill. There was marked periorbital edema, and some

puffiness over the hands and forearms. An irregular, symmetrical, bright erythematous eruption, sharply demarcated from the surrounding skin, was present over the forehead, perinasal area, cheeks and chin. A more diffuse, pigmented eruption was present over the neck posteriorly and on the abdomen. The hands, forearms and shoulders revealed a raised, red, papular eruption, both discrete and confluent, which was most pronounced on the extensor surfaces and around the nails. The lungs were clear, and the heart, except for a soft blowing systolic murmur over the entire precordium, was normal. Neurologic examination revealed some muscular weakness of the back, the arms and, to a lesser degree, the legs. There was no evidence of atrophy, ataxia or tremor. The gag reflex was absent on the right and practically absent on the left. All the deep tendon reflexes were present and equal. Sensory tests were normal.

The temperature was 98.8°F., the pulse 90, and the respirations 20. The blood pressure was 145 systolic, 70 diastolic.

Examination of the blood showed a red-cell count of 4,400,000, with 14.7 gm. of hemoglobin. The white-cell count ranged from 4300 to 8900, with 64 to 74 per cent neutrophils, 18 to 29 per cent lymphocytes, about 6 per cent monocytes and 1 per cent eosinophils. Examination of the urine revealed only a few white cells in the sediment. The serum non-protein nitrogen level was normal, and the protein 6 gm. per 100 cc. The van den Bergh and cephalin flocculation tests were negative. A bromsulfalein test showed 15 per cent dye retention. The Hinton and Wassermann tests were repeatedly positive. A lumbar puncture revealed clear fluid under an initial pressure equivalent to 165 mm. of water. The Wassermann test was positive, and the gold-sol curve was 0011100000. A heterophil agglutination test, skin tests with trichinella antigen and blood cultures were negative.

A roentgenogram of the chest was normal. A Graham test revealed no filling of the gall bladder with dye, and there was a 4-cm. laminated stone in the area.

Over a period of several months, the patient continued to complain of extreme muscle weakness and ran a low-grade fever, usually below 100°F. A therapeutic test with 0.5 mg. of Prostigmine produced no change in symptoms. The eruption, especially that on the face, shoulder and back, became more pronounced and dusky in color and was associated with some edema about the eyes. Numerous transfusions were given. Several infected decubitus ulcers developed on the buttocks and over the right elbow. These were treated with sulfadiazine and azochloramid packs. About five months after admission the patient began to complain of distressing gas pains and diarrhea, with four to five rather loose stools daily, on which guaiac tests were negative. At that time, examination

revealed a firm, slightly movable mass in the right upper quadrant, descending with respiration. A rectal examination revealed a small ulcer on the anterolateral wall, which was confirmed by proctoscopy. The edges were thickened and irregular, and the ulcerated area bled on slight trauma. The mucosa of the remainder of the rectum was finely granular and indurated, but no other ulcers were seen. A biopsy of the ulcerated area revealed acute inflammation.

Following this episode the patient began to improve in appearance and spirits. She received 25 mg. of testosterone propionate intramuscularly every two days, but it was noted that the tendency to the improvement antedated this treatment. A gastrointestinal series was made at the beginning of the eighth hospital month. The patient swallowed the barium mixture without difficulty. The esophagus, stomach and small intestine failed to reveal any definite variation from the normal. The gallstone previously described was still present. A barium enema revealed an area of narrowing at the rectosigmoid junction, extending for a distance of 1 cm. This was never seen to dilate more than 1.5 cm.; it did not change in appearance and revealed no areas of ulceration. No other abnormality was seen.

Following the patient's striking improvement, associated with increase in weight, well-being and ability to get about by herself, she was discharged to a nursing home at the end of the ninth month.

Second admission (five weeks later). A few days after her arrival at the nursing home the patient developed spells of vomiting once or twice daily, usually after meals. These were rapidly followed by loss of strength, and she lost 10 pounds in the interval. The vomitus was never black or bloody, nor was there any jaundice or fever. There was mild constipation. Four days prior to admission she developed severe, diffuse, lower abdominal pain and cramps, relieved by the passage of gas. On several occasions she passed a loose stool, together with considerable gas but no blood. The vomiting continued. On the day prior to entry she developed a fever (about 102°F.) for the first time since her discharge.

Physical examination revealed an emaciated woman in moderate distress. The skin showed dry areas of whitening and brownish pigmentation over the face, chest, back and hands. The musculature was atrophic. The lungs were clear. The abdomen was moderately protuberant and exquisitely tender, especially in the lower quadrants. Rebound tenderness was present, but there was no spasm, nor were any masses palpable. Peristalsis was greatly diminished. There was tenderness over both costo-vertebral angles. A pelvic examination revealed marked tenderness on manipulation of the cervix. Rectal examination showed a questionable ulceration just inside the sphincter on the anterior wall.

The temperature was 101.6°F., the pulse 100, and the respirations 20. The blood pressure was 110 systolic, 60 diastolic.

Examination of the blood revealed a red-cell count of 5,500,000, with 100 per cent hemoglobin, and a white-cell count of 11,900, with 85 per cent neutrophils, most of which were band forms. The urine was normal. The serum nonprotein nitrogen level was normal, and the protein was 6.6 gm. per 100 cc.

A roentgenogram of the abdomen revealed numerous dilated loops of small bowel, and gas was present in the stomach. X-ray examination of the chest revealed little change in the lung fields, but the heart appeared to have increased in size.

A Miller-Abbott tube was passed into the jejunum, and dextrose in water and normal saline solution were administered intravenously. Sulfadiazine was also administered, together with several transfusions. By the eighth hospital day the temperature was normal, and examination of the abdomen revealed normal peristalsis. Tenderness in the lower quadrants was reduced and she had several normal bowel movements. Hourly films of the small bowel showed slight delay in transit, seven hours being required for the barium to reach the colon. There was no definitely abnormal dilatation of the small bowel when barium was present in the loop, but on some of the films there appeared to be dilatation, mucosal irregularities and loss of pattern before the barium entered the loop.

Two days later the temperature rose to 103.2°F. She passed a stool consisting of mahogany-colored fluid with a ++ guaiac reaction, followed on the next day by a semisolid, brown, guaiac-negative stool. The abdomen was generally tender, with rebound tenderness and mild spasm. Rectal examination revealed several extremely tender shallow ulcerations just inside the anus anteriorly; they had the appearance of fistulas. A Levine tube was passed, and 400 cc. of black watery fluid, becoming thick and tarry, was aspirated. The guaiac reaction on this material was ++++. Many rales were audible over both lung bases, and the pulse was rapid. An x-ray film of the chest, taken with the portable machine, revealed linear areas of increased density in the right upper and left midlung fields. An electrocardiogram revealed low voltage in the standard leads, with flat T₁, low to diphasic T₂, slightly inverted T₃ and inverted T₄; R₁, R₂ and R₃ measured 3, 2 and 2 mm. respectively, and S waves were absent.

The patient rapidly became comatose and died on the fourteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES: My first reaction to this interesting story was that the total picture might have been due to tuberculosis. We know that the patient had gallstones, on the basis of a history of biliary colic and x-ray evidence of stone. We also

know that the patient had syphilis, on the basis of numerous positive serologic tests. Arsenical treatment for syphilis was initiated just about the time that the first skin lesions appeared, and it may be of some interest to speculate on the possible role of arsenic in causing the skin lesions. The exposure to tuberculosis in various members of the family is also of interest. Careful evaluation of the progress of symptoms, which started some months prior to the skin eruption, leads me to believe that the gallstones and the syphilis had nothing to do with the fundamental picture as it unfolded. The possible role of tuberculosis remains to be considered. The patient had a story of almost a year's duration, with marked skin changes, intermittent fever and a final elevation of temperature. Furthermore, there was a definite story of rectal ulceration, and a terminal story of that as well as the picture of peritonitis, which makes me think that she had perforated one of the rectal ulcers or one higher up in the colon. She had a rectal stricture and, in addition, a story from the very beginning of progressive muscular weakness and atrophy. The cause of the terminal hematemesis is obscure.

Is there any single diagnosis, aside from gallstones and syphilis, that covers all the facts? If we tie them all together one has to think in terms of tuberculosis, with skin lesions, with gastrointestinal lesions and possibly, because of the rales in the chest, a hematogenous spread at the last moment and a resultant miliary tuberculosis. I am not entirely happy with such an explanation. Syphilis, it seems to me, could explain this picture by stretching one's imagination to the limit. She could have had a rectal stricture due to syphilis. She had a positive spinal-fluid Wassermann reaction, but there were no signs or symptoms of syphilis of the central nervous system. She had a negative gold-sol curve, and there was no increase in the spinal-fluid cell count or protein. It is hard for me to believe that she had central-nervous-system syphilis. There is no evidence that points strongly to cardiovascular syphilis, and syphilis that would produce rectal stricture, ulcers, bleeding and peritonitis is something that I have not seen. I suppose it can occur, because anything can happen with syphilis; but it is not a logical diagnosis. What other things can cause stricture besides syphilis? We may think of it in terms of lymphogranuloma inguinale, but the remaining symptoms are not those of this disease.

If we start with the skin lesions, which I am not qualified to discuss, I should merely say that the erythematous lesions appeared rather suddenly, with muscular weakness, periorbital edema, loss of weight and gastrointestinal symptoms that for the moment we shall leave out. One has to think of lupus erythematosus disseminatus, scleroderma and dermatomyositis. These three diseases ought to be considered in view of the peripheral mani-

festations. I think possibly that each of these conditions could cause that part of the picture. No skin biopsy was taken, although she was in the hospital for nine months; at least there is no record. If it was diagnostic, it may have been omitted purposely. Skin and muscle biopsies of dermatomyositis at the proper stage of the disease, which, as I understand it, is late in the course of the disease, are distinctive and show a degenerative process. There is edema around the muscles, and subcutaneous edema, which can be demonstrated histologically as well as clinically. In scleroderma one observes edema under the skin and thickening, but not the histologic picture of muscular degeneration that is seen in dermatomyositis. In disseminated lupus, except as a wasting disease, I do not believe that one expects muscular atrophy. I am sure that the attention of an expert skin pathologist is required before one can be dogmatic about the diagnosis of disseminated lupus on a skin biopsy. I believe that periorbital edema is likelier to be present in dermatomyositis than in scleroderma or in disseminated lupus. I shall hazard the guess that if this were disseminated lupus over an entire year's period the patient should have had a more elevated temperature than she did have, although I should be glad to be corrected on that point. Muscular weakness is characteristic of dermatomyositis in a large number of patients and at times mimics myasthenia gravis. We know that the diagnosis of myasthenia gravis was considered because the patient was given Prostigmine as a therapeutic test. Five tenths of a milligram is the usual dose, is it not, Dr. Ayer?

DR. JAMES B. AYER: Yes. -

DR. JONES: It produced no change, and it would be unusual for myasthenia gravis not to respond to such a dose. I think this diagnosis can be dismissed. Furthermore, the whole course of the disease is not too consistent with myasthenia gravis, although the patient did have progressive muscular weakness.

In considering scleroderma, there are one or two other things that I can add in a hesitating fashion. We do know that one observes gastrointestinal lesions in scleroderma, and as Hale¹ and others have shown, evidence of generalized stiffness and edema and a fibrotic condition involving the esophagus, with a lack of normal peristaltic activity. Ulcerative lesions have not been described in the gastrointestinal tract in scleroderma to the best of my knowledge. Whether dermatomyositis can be associated with similar lesions, I do not know. It is a queer disease, and I am sure that we do not know all its manifestations. Scleroderma is also a queer disease, about which we know very little. Disseminated lupus, to my knowledge, is not associated with ulcerative gastrointestinal lesions. That very fact, if I am going to stick to one diagnosis, rules

out lupus, along with other things that I have mentioned.

Tuberculosis with queer skin manifestations can certainly answer this diagnostic problem. Ulcerations of the gastrointestinal tract are not too infrequent in tuberculosis and can produce, after healing, a stricture of the rectum. It is hard for me to make a single diagnosis that covers all the findings, but what I can do is to indicate the possibilities that occur to me. The terminal event, I think, was the final episode of a prolonged disease, with perforation of an ulcer and peritonitis; on the other hand, the terminal cause of death may have been a coronary accident. The linear shadows in the chest suggest pulmonary emboli, which may have occurred late in the illness. In dermatomyositis one often observes electrocardiographic changes suggesting involvement of the myocardium, as well as that of the voluntary muscles. I am not at all certain that these changes are diagnostic, but I believe they have been reported. Excessive sweating is one of the interesting phenomena supposed to take place in dermatomyositis.

That is as far as I can go without making rash statements that have no meaning whatever. I shall therefore say that this patient had gallstones and probably cholecystitis, both of which had nothing to do with the rest of the picture. I believe that she had syphilis; I am sure that such a diagnosis does not explain the whole setup, and as near as I can come to tying it in is to say that the rectal fistula might have been syphilitic in origin. Beyond that I believe that she had one of the three conditions that I have mentioned — dermatomyositis, scleroderma or disseminated lupus erythematosus. Of the three, I shall put dermatomyositis first, admitting that I know nothing about the gastrointestinal lesions in that disease. I shall choose scleroderma as a close second, because I know that digestive-tract lesions have been found on several occasions in this curious disease. It may well be that there was tuberculosis as an added factor, which would help to explain the gastrointestinal symptoms, but it had nothing to do with what originally brought her to the hospital.

I am a little intrigued by the statement, or by the fact, if it is a fact, that some of the skin lesions appeared after two doses of Mapharsen. It is possible that inadequate antisyphilitic treatment was associated with syphilitic skin lesions that can behave this way when latent syphilis is treated inadequately. I cannot explain the skin lesions on the basis of reactivation of the syphilis or on the basis of syphilis itself, except the papular lesions, which were rather odd.

I should like to see the x-ray films. I do not believe that she had tuberculosis of the stomach, which is exceedingly rare and mimics cancer.

DR. MILFORD D. SCHULZ: This is certainly a curious small-bowel pattern (Fig. 1). There is some edema of the wall. The picture is much like what Dr. Hale has described in scleroderma.¹ None of the bowel loops seem to be fixed in relation to one another for any period of time, as one would expect to see if the patient had had tuberculous peritonitis.²

DR. JONES: One might add that that fits in with the story that she was depleted from apparent partial intestinal obstruction. It took nine hours for barium to go through the intestinal tract, which implies that the motor activity of the small bowel

DR. JONES: Was the balloon put in to hold the barium in the colon in order to take the picture?

DR. SCHULZ: I think that it was.

DR. JONES: In that case it suggests an atonic anal sphincter, a condition often associated with dermatomyositis or scleroderma.

DR. SCHULZ: Or syphilis.

DR. JONES: What about the linear shadows in the chest film? Do they suggest infarction?

DR. SCHULZ: Here are two that suggest scars of old infarcts; such a lesion was apparently not present on the films taken eleven months previously.

FIGURE 1. Roentgenogram Showing the Distribution of Barium in the Small Bowel Six Hours after Administration.

Note the evidence of slow transport and of mucosal swelling.

was interfered with by some intrinsic nerve disorder or by an infiltrative process.

DR. SCHULZ: The fluoroscopist could have better described the findings, but the barium-filled esophagus looks wide and stiff — a lead-pipe appearance. It may have contracted later, but it had not at the moment when these films were made.

DR. JONES: Have you a picture that shows the rectal ulceration and stricture? That worried me more than anything else.

DR. SCHULZ: Here is a film after a barium enema. The ulcer seems to be in the sigmoid. The rectum appears normal. Of course there is a balloon in it, and the normal rectum does not balloon out to that size without protest.

DR. JONES: You can see no evidence of recent infarcts?

DR. MAURICE FREMONT-SMITH: One argument for scleroderma is the tenderness over the areas of edema. I do not believe that Dr. Jones brought that out. Furthermore, an argument against lupus is the absence of albumin and red cells in the urine. I also do not know whether intestinal symptoms go with the strange disease called dermatomyositis.

DR. BENJAMIN CASTLEMAN: Dr. Lever, will you comment, from the dermatologic point of view, on the differences between these two diseases.

DR. WALTER F. LEVER: From the standpoint of the dermatologist, the diagnosis in this case lay between lupus erythematosus and dermatomyositis,

rather than between scleroderma and dermatomyositis. For a diagnosis of scleroderma, one expects a certain amount of boardlike induration of the skin and subcutaneous tissue, which was absent in this patient. The cutaneous lesions were suggestive of lupus erythematosus in that there were erythema and atrophy, but the same type of lesions can be found in dermatomyositis. In favor of dermatomyositis was the presence of tenderness over the involved areas of skin, and also the muscular tenderness. In scleroderma, muscular atrophy may be just as severe as in dermatomyositis, but usually it is not combined with tenderness of the muscles. So, from the dermatologic point of view, the diagnosis was dermatomyositis.

CLINICAL DIAGNOSES

Dermatomyositis, generalized.

Generalized peritonitis.

Acute pancreatitis?

Mesenteric thrombosis?

DR. JONES'S DIAGNOSES

Dermatomyositis or scleroderma.

Peritonitis, following perforation of the colon.

Old pulmonary infarcts.

Cholelithiasis.

Syphilis.

ANATOMICAL DIAGNOSES

Dermatomyositis.

Ulcers of esophagus, jejunum and rectum, with perforation of several jejunal ulcers.

Fibrous and myxomatous intimal proliferation of intestinal arteries, with thromboses.

Abscess, pelvic, right.

Peritonitis, acute, fibrinopurulent.

Bronchopneumonia.

Lipid pneumonia.

Arteriosclerosis, generalized.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: As Dr. Jones inferred, a biopsy had been done at the time of the first admission and the diagnosis of dermatomyositis was established. The autopsy also showed what Dr. Jones predicted. This woman had a perforation of the intestine, with acute purulent generalized peritonitis. Numerous sections of striated muscle throughout the body showed severe degeneration. In some areas there was no cellular infiltration, but in others it was marked. There is no question about the diagnosis of dermatomyositis.

The intestinal tract was unusual, and as could be seen from the roentgenogram of the gastrointestinal series, the small intestine, especially the jejunum, was markedly edematous. Throughout the jejunum were numerous ulcers, some tiny and others measuring up to 1 cm. in diameter. A few of these had perforated and had produced peritonitis. There were also ulcers in the rectum that were similar to those seen in the jejunum, but we

did not find any evidence of stricture. There were no ulcers in the duodenum or other parts of the colon, but the entire bowel was markedly edematous, thick and brawny. Microscopic examination showed

FIGURE 2. Photomicrograph of One of the Ulcers of the Small Intestine.

Note the extensive arterial disease in the submucosa.

that most of the edema was in the submucosa. The bases of the ulcers were covered with fibrin and an extensive lymphocytic and polymorphonuclear leukocytic infiltration (Fig. 2). In the edematous

FIGURE 3. Photomicrograph at a Higher Magnification of One of the Vessels in the Submucosa.

Note the marked intimal proliferation with luminal narrowing.

submucosa beneath the ulcers, and also in regions that were not ulcerated, the large vessels showed pronounced fibrous and myxomatous intimal proliferation with marked luminal narrowing (Fig. 3). Some of the vessels were completely occluded, and

others contained recent or organized thrombi. The ulcers were almost certainly the result of the vascular disease. An occasional vessel showed organized thrombosis with recanalization (Fig. 4). These vascular lesions were found only in the intestines. We hunted throughout the sections of the various other organs but were unable to find anything similar to the lesions found in the intestine. They duplicated the changes seen by Dr. Gall in the kidneys of a case of dermatomyositis that we had several years ago.³ In that case, the myxomatous intimal lesion was found only in the kidneys. The kidney sections in this case were perfectly normal, except for evidence of mild arteriosclerosis, certainly

FIGURE 4. Photomicrograph of Another Vessel.
Note the thrombosis with recanalization.

nothing that simulated the vascular changes that were found in the intestines.

DR. JONES: What did you find in the heart?

DR. CASTLEMAN: Nothing. There was no degeneration. We have recently gone over all our cases of dermatomyositis and were unable to find any definite change in the heart muscle. In one case the myocardial findings were equivocal.

DR. FREMONT-SMITH: Do you call this whole disease process dermatomyositis? Is it all part of the same picture?

DR. CASTLEMAN: I believe so.

DR. MARIAN ROPES: Clinically, I have noted intestinal symptoms in at least two other cases with long periods of severe diarrhea. Such cases usually do not have guaiac-positive stools and do not reach this picture by x-ray.

DR. JONES: I should like to ask if gastrointestinal lesions have been described in dermatomyositis. That is an important point.

DR. LEVER: They have been described in a few cases. In Potain's⁴ case, the autopsy revealed multiple visceral infarcts. In the case reported by Karelitz and Welt,⁵ diffuse enterocolitis with intestinal ulceration was encountered. The arteries of the small intestines showed marked edema and round-cell infiltration between the fibers of the muscular layer. The case cited by Schuermann⁶ presented hemorrhages into the mucosa of the stomach, with early necroses, as well as erosions in the lymphatic tissue of the lower small bowel. Vascular lesions were absent.

DR. CASTLEMAN: Because of the dermatomyositis, these patients are prone to have trouble in swallowing, as this patient had. The administration of mineral oil should be avoided, lest some of it pass down the larynx and into the lungs. This patient must have been taking mineral oil for some time, because we found a great many foci of lipid pneumonia throughout all lobes, especially the lower ones.

DR. JONES: Do you want to comment on the difference between this and scleroderma? Are the lesions of scleroderma like this?

DR. CASTLEMAN: I do not recall a case of scleroderma with bowel lesions. I have just seen a report that describes marked atrophy of the musculature of the gastrointestinal tract but no vascular lesions similar to those in this case of dermatomyositis.⁷

DR. JONES: Certainly the number of patients with scleroderma who have gastrointestinal symptoms and x-ray signs is much larger than that of those with dermatomyositis.

CASE 31102

PRESENTATION OF CASE

A seventy-seven-year-old widow entered the hospital because of marked dyspnea, abdominal distention and tenderness in the right upper quadrant.

Nine years before admission she had a subtotal thyroidectomy for nontoxic goiter, 140 gm. of tissue

having been removed. The pathological report was "hyperinvoluted." After recovery she lived at a home for aged women, where her activities were limited. Five years before admission she received some medical attention for "gall-bladder trouble" and "a heart condition." She had at that time only shortness of breath and could not take digitalis because this caused vomiting. She spent nine weeks in bed and was well thereafter. Three months before admission she began having pain in the right upper quadrant, which came on only after lying in bed. This pain lasted up to two hours, varied in severity and had no relation to food or exertion. Long-standing constipation became accentuated and required an additional laxative tablet each day. Four days before admission she entered the Emergency Ward because of painful migratory arthritis involving both feet and the right hand. Physical examination and x-ray study at that time were consistent with rheumatoid arthritis. She was discharged to the Out Patient Department. One day before admission, distention of the abdomen began after an unsuccessful enema had been given and the patient's dyspnea increased. Repeated enemas resulted in several loose movements, without relief of the distention or the dyspnea. On the day of admission she had had two episodes of vomiting.

Physical examination revealed a dyspneic woman in moderate discomfort but without pain. The lips, ears and mucous membranes were cyanotic. The heart was not enlarged, and the sounds were normal. The neck veins were slightly distended and pulsating. Bilateral crackling basal rales were heard, and in the same areas there was increased dullness to percussion. There was no peripheral edema. The abdomen was markedly distended and tympanitic. Peristalsis was diminished. There was tenderness in the right upper quadrant. No abdominal splinting or masses were noted. Rectal examination was negative. The rectum was filled with soft, tan feces, which were guaiac negative.

The rectal temperature was 100°F., the pulse 84, and the respirations 20. The blood pressure was 168 systolic, 80 diastolic.

Examination of the blood revealed a red-cell count of 3,800,000, with 10.5 gm. of hemoglobin, and a white-cell count of 16,000, with 91 per cent neutrophils. The urine was acid and had a specific gravity of 1.016, with a +++ test for albumin and occasional white cells and casts. The Bence-Jones protein was negative. The serum nonprotein nitrogen was 42 mg. per 100 cc., and the total protein 5.8 gm., with an albumin-globulin ratio of 1.1. The carbon dioxide and chloride levels were normal. The phosphorus was 1.4 mg. per 100 cc., and the alkaline phosphatase 10.6 Bodansky units.

X-ray films of the chest showed mottled areas of increased density scattered throughout the lungs.

The vascular shadows were increased in size. The heart was prominent in the region of the left ventricle and the aortic tortuosity. Films of the abdomen showed considerable gas in the small and large bowel, neither of which appeared to be dilated. There was a laminated gallstone in the region of the gall bladder. No abnormal soft-tissue masses were seen. An electrocardiogram showed normal rhythm at a rate of 75, a PR interval of 0.16 second, a flat T₁, upright T₂ and T₃, and a biphasic T₄, with a sagging ST₄. The patient was digitalized with Cedilanid and was given sulfadiazine.

On the second hospital day the patient was considerably improved and was no longer orthopneic, dyspneic or cyanotic; the lungs had cleared but a few patches of fine rales persisted at both bases posteriorly. The abdominal distention was diminished, and two masses in the right upper quadrant could be felt 5 to 7 cm. below the costal margin. These were nontender and descended with inspiration; they were thought to be due to a coarsely irregular liver edge. The sulfadiazine level was maintained at about 10 mg. per 100 cc., with an intake of about 1250 cc. and an output of about 1000 cc.

At 12:30 a.m. on the fifth hospital day she had an episode of steady precordial pain with gradual onset. Moderately severe orthopnea, with a respiratory rate of 40, lasted about twenty minutes. Repeated electrocardiograms showed inverted T₁, T₂, and T₃, and a sagging of all ST segments. X-ray films of the chest on the same day showed that the mottled areas of increased density previously described had cleared considerably. Only moderate congestion of the vessels was noted, and no infarcts were seen in a posteroanterior view. The nocturnal dyspnea recurred during the succeeding two nights. There was no increase in the pulmonary rales.

A bromsulfalein test on the fifth hospital day, using 5 mg. of the dye per kilogram of body weight, showed 80 per cent retention in forty-five minutes. A van den Bergh test was normal. An aspiration biopsy of the liver showed no abnormality. The cephalin flocculation test was + in forty-eight hours. A barium enema was negative.

The white-cell count rose steadily and reached 31,400 on the eleventh hospital day, with 75 per cent neutrophils, 5 per cent lymphocytes, 4 per cent eosinophils and 16 per cent large monocytes. A low-grade fever (99 to 100°F.) and anemia persisted. The stools were brown and formed. The urine persisted in showing a +++ to ++++ test for albumin and a specific gravity of 1.006 to 1.020.

On the twelfth day the patient suddenly had an attack of acute pulmonary edema, for which she was treated with tourniquets, morphine, Cedilanid and, finally, venesection. She rallied but developed peripheral edema. She became incontinent, with slowly increasing depression and unresponsiveness, and died on the twenty-third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. REED HARWOOD: Whatever else we are dealing with in this case it is evident that the patient had congestive heart failure. I think that two questions should be considered—first, the type of heart disease that was responsible for the failure and, second, whether any further disease contributed to her death.

Nine years before admission she had a subtotal thyroidectomy. This raises the question of myxedema. If she did have myxedema it is not evident from the record.

Four days before admission she came to the Emergency Ward, complaining of painful migratory arthritis. It is unusual but not impossible to see acute rheumatic fever in a person of this age; I have seen it in persons of fifty years. One would expect, however, to find an increased PR interval in the electrocardiogram and to have more statements about her joints after she was admitted to the hospital.

The low-grade fever and the anemia suggest a subacute bacterial endocarditis, but I consider that as remote. She was an old woman who had a moderate hypertension. The x-ray films showed some enlargement of the left ventricle, and I think it is likely that she had hypertensive heart disease. At her age it is reasonable to expect that she had sclerosis of the coronary arteries. I suggest that she had a combination of hypertensive and arteriosclerotic heart disease.

The initial electrocardiogram was not strikingly abnormal, and I am interested to see if the changes that took place were consistent with an infarct. She was given digitalis, and we therefore expect to find sagging of the ST segments. I cannot say with complete confidence, however, that these tracings are consistent with an infarct. But since, following the attack of precordial pain, there was a definite change in CF_4 , it seems extremely likely that she had a myocardial infarct.

In answer to the first question, that is, the type of heart disease responsible for failure, I believe that she had hypertensive and arteriosclerotic heart disease, with a small myocardial infarction while she was in the hospital.

Did she have anything else that contributed to her death? She had abdominal pain and constipation shortly before admission; she was found to have a secondary anemia and a persistent +++ test for albumin, without striking abnormalities in the urinary sediment. The attending physicians evidently considered the possibility of multiple myeloma because of the marked albuminuria and anemia, but the test for Bence-Jones protein was negative and the serum protein was not markedly increased. I do not believe that this entirely rules out multiple myeloma, but at least the evidence is against it. It was found that she had a phosphorus

of 1.4 mg. per 100 cc. and an alkaline phosphatase of 10.6 Bodansky units, both of which are abnormal figures. The only condition that I know of in which the phosphorus is reduced to such a low figure is hyperparathyroidism, but that may be ignorance on my part. If at post-mortem examination an adenoma of the parathyroid gland was found, I should be willing to give the opinion now that it did not contribute to her death. I am inclined to think that she did not have an adenoma, because there is so little evidence to go with it. The alkaline phosphatase was definitely increased, which suggests some disease of the bone in which the osteoblastic activity is increased. Once again one thinks of hyperparathyroidism, Paget's disease or some type of malignant disease involving the bone.

Another finding is the presence of two masses in the right upper quadrant. For lack of a better explanation I decided that she had a liver that was probably engorged from early right-sided failure of the heart and a chronically inflamed gall bladder. Both masses were rather low in the abdomen, at least four fingerbreadths below the costal margin. She might conceivably have had a diseased kidney on that side.

We next come to the consideration of disease of the liver, about which there are many contradictory data. Evidently the attending physicians thought that she had liver disease. They did a bromsulfalein test on the day that she had acute left ventricular failure and found that she had 80 per cent retention. At the same time a van den Bergh test was normal. A biopsy of the liver was normal, and a cephalin flocculation test was not definitely abnormal. The serum protein level and the albumin-globulin ratio were normal. With all this negative evidence I am going to disregard the bromsulfalein test or at least not give it undue importance. I do not know what happens to the bromsulfalein test in cases of congestive failure, but it is at least possible that during acute congestive failure more of the dye would be retained.

Finally, there was a peculiar reaction of the bone marrow, which had produced a leukocytosis by the twelfth hospital day. I should like to know about some of the other white-cell counts and differentials during the preceding interval.

DR. BENJAMIN CASTLEMAN: On admission, the white-cell count was 16,000; subsequently, it was 13,000, 18,000, 23,000 and 31,000; on the tenth day it was 32,000, and then 18,000 and 32,000. In the differential counts the neutrophils ranged from 91 to 74 per cent, and then from 71 to 77 per cent.

DR. HARWOOD: When did the monocytosis appear?

DR. CASTLEMAN: On the tenth day, there were 5 small lymphocytes and 3 monocytes; on the fifteenth day, 5 small lymphocytes, 6 large lymphocytes and 3 monocytes; three days later, 4 large lymphocytes, 9 small lymphocytes and 8 monocytes, with 2 myelocytes.

DR. WYMAN RICHARDSON: There were numerous smears interpreted by different persons.

DR. JAMES A. ROTH: The monocytes were not typical. They were large mononuclear cells, which I could not classify. They stained light blue.

DR. HARWOOD: I should like to ask Dr. Schulz if there is anything in the chest plate to suggest any disease other than congestive failure.

DR. MILFORD SCHULZ: The pulmonary markings are prominent. They do not look just like the prominent markings that are seen with lymphatic spread of a tumor. There is not much fluid in the chest. In the lateral view there is a triangular shadow in the posterior gutter that could indicate an infarct, but it is not entirely characteristic.

DR. HARWOOD: Do you want to say anything about the bones?

DR. SCHULZ: All the bones are decalcified but no more than one would expect in a person of her age. There is no evidence of cysts, and no change in the vertebral bodies. There are old arthritic changes in the hands and feet. I do not see any localized areas of destruction.

DR. HARWOOD: Is there anything suggestive of miliary tuberculosis in the lungs?

DR. SCHULZ: The picture is not consistent with that of miliary tuberculosis. Lungs that look like this are disturbing. One thinks of passive congestion, early lymphatic spread of malignant disease, pulmonary fibrosis and even miliary tuberculosis; something similar is often seen in diseases like periarteritis nodosa.

DR. HARWOOD: Do you see anything in the lungs that suggests the need for sulfadiazine? The temperature was 100°F. when the patient came in, and she had a high white-cell count. There is nothing in the record, however, to give me a clue why sulfadiazine was necessary, and this raises the question why patients have to be treated with some kind of chemical. We know that occasionally a fever subsides without their use, and I doubt that this patient needed sulfadiazine. I shall proceed, leaving the statement for what it is worth.

To go on with the discussion, I think that some other disease besides heart disease was found post mortem. I have no idea what, but the evidence points to a lesion that involved bone. I should think, first of all, of a malignant tumor with widespread metastasis, including involvement of the lungs. The original site of such a tumor I cannot determine. It may have been the thyroid gland, the gall bladder or some other intra-abdominal organ.

Another possibility is miliary tuberculosis. The evidence for this is not striking. I also thought of the possibility of some acute intra-abdominal catastrophe to explain the increasingly high white-cell counts, such as thrombosis or embolus of some vessel or perhaps perforation of the gall bladder.

I remember a patient with carcinoma of the prostate who developed a high fever and chills. I thought that he had a kidney infection, but at post-mortem examination we found that the gall bladder had ruptured into the bed of the liver, discharging a hundred or more small stones. It was an entirely unsuspected finding. In the present case, I also thought of the possibility of disease in the liver. The likeliest lesion would be a metastatic carcinoma.

DR. RICHARDSON: I did not see this patient, but I did see a blood smear taken at about the midpoint of her illness. At that time she had received sulfadiazine for some time. The picture was that of a considerable degree of leukocytosis. There was no evidence of infection from the smear. There were some peculiar cells, which might have been very immature red cells, and I thought that the whole picture might have been due to sulfonamide therapy. Sulfonamides had been stopped, however, a few days previously, but still the total white-cell count remained elevated. There was also red-cell regeneration. I wrote in my note that since the picture had continued after the stopping of sulfonamides it was quite consistent with involvement of the bone marrow, presumably by a malignant tumor that had also produced considerable anemia. There were no toxic changes such as are usually seen in uremia, nor was it hypochromic by measurement. It was a "simple anemia" but must be explained somehow.

Not knowing the answer in this case, I should say that the patient probably had malignant involvement of the bone marrow. The possibility of myeloma should be considered. Those queer cells might conceivably have been immature plasma cells.

DR. CHESTER M. JONES: I should like to take minor exception to one statement that Dr. Harwood made, namely, that an elevated phosphatase means disease of bone. That is not correct because an elevation of the phosphatase level may also occur in liver disease and may be as high or higher than that noted in involvement of bone.

DR. HARWOOD: Is that true in patients without jaundice?

DR. JONES: Yes.

Dr. Harwood was entirely right in stating that the elevation of the bromsulfalein retention could be explained by congestive failure. No doubt one could observe dye retention, positive cephalin flocculation and Takata Ara tests and at least some change in the albumin-globulin ratio as a temporary episode occurring with congestive failure. On the other hand, 80 per cent retention in forty-five minutes is extremely high.

I do not recall this case too well, since the patient came in at a time when I was out of the hospital for a few days. I do recall, however, that we entertained the thought of metastatic cancer of the liver as a real possibility and that is why the biopsy was

done. The fact that nothing was found on aspiration biopsy is no proof against its existence. One can miss a nodule very easily.

CLINICAL DIAGNOSIS

Metastatic carcinoma to lungs and liver?

DR. HARWOOD'S DIAGNOSES

Hypertensive and arteriosclerotic heart disease, with congestive failure.

Carcinoma of gall bladder or thyroid gland, with metastases to bone marrow?

ANATOMICAL DIAGNOSES

Carcinoma of gall bladder, with extension into liver and with metastases to lung, liver, peritoneum and bone marrow.

Cardiac hypertrophy, hypertensive type, slight. Cholelithiasis.

Hydrothorax, slight, bilateral.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The post-mortem examination disclosed a heart weighing over 400 gm., with slight

hypertrophy of the left ventricular wall, which is consistent with a mild hypertensive heart. There was no infarction, and the coronary arteries were only slightly sclerotic. We found no real evidence of heart failure. There was about 50 cc. of fluid in both pleural cavities. The liver showed no evidence of chronic passive congestion, but it was enlarged. In the region of the gall bladder was a mass about 6 or 8 cm. in diameter that completely replaced the gall bladder and that looked like carcinoma. It extended into the liver substance for about 4 or 5 cm. In cutting through this mass we found a gallstone embedded within. Microscopic sections revealed that this was a primary carcinoma of the gall bladder. The increase in pulmonary markings was due to metastatic carcinoma.

DR. RICHARDSON: What about the bone marrow?

DR. CASTLEMAN: There were also metastases to the peritoneum and to the bone marrow.

DR. SCHULZ: Was the entire bone marrow replaced?

DR. CASTLEMAN: We have not seen enough sections to say, but the one section that I examined certainly showed extensive involvement.

DR. JONES: This woman was given sulfonamides with the idea that she had a bacterial pneumonia.

done. The fact that nothing was found on aspiration biopsy is no proof against its existence. One can miss a nodule very easily.

"KEEP 'EM ALIVE IN 'FORTY-FIVE"

It has been well said that instead of trying to make ourselves happier and other people better, we should make ourselves better and other people happier. The American Red Cross, which is now conducting its annual War Fund drive, is making a great many people happier—or at least much less miserable. In so far as the Nation supports its endeavors, we shall be a better people. Immediate incentives are the mounting casualty and prisoner-of-war lists, and the enthusiastic endorsement of the Red Cross by military and naval leaders. The number of chapters in Greater Boston—twenty-two—amalgamated for the drive is the

THE "PSYCHONEUROTIC"

SOME TIME sportswriter Bill Cunningham has acquired new stature as he has found new fields in which to try his strength. In the January 21 issue of the *Boston Herald* he took his fling at the stubbornly cherished belief that a diagnosis of psychoneurosis, particularly when it has been applied to a soldier, constitutes a stigma denoting mental deterioration or moral weakness. Grave injustices are being done to many thousands of innocent and capable young men who are being prejudiced in their opportunities to re-enter industry and normal civilian life, and it is at least partly the job of the country's doctors to educate the public to a better understanding of the profession's more commonly used terminology. To the lay mind, apparently, any word containing the root "psycho" (from the Greek, meaning soul; derived from the word *Psyche*—a lovely maiden with wings like a butterfly) implies organic disease of the soul or mind, in other words, insanity—and there seems to be no doubt in Greek mythology that Cupid was crazy about *Psyche*.

The shell shock of World War I, which was an induced psychoneurosis, was considered to have been brought about by physical forces and consequently was an illness that respectable soldiers could have. The same forces, acting on the mind

most generous extent possible. who can contribute to the drive to do so, and to the cent over the previous year, so that it behooves all budget for 1945 represents an increase of 12.5 per couldn't get along without it." The Red Cross however has said of the organization, "We simply widely known to require emphasis. General Eisenhower has said of the organization, "We simply couldn't get along without it." The Red Cross budget for 1945 represents an increase of 12.5 per cent over the previous year, so that it behooves all who can contribute to the drive to do so, and to the

DR. SCHULZ: Was the entire bone marrow replaced?

DR. CASTLEMAN: We have not seen enough sections to say, but the one section that I examined certainly showed extensive involvement.

DR. JONES: This woman was given sulfonamides with the idea that she had a bacterial pneumonia.

NOTICES

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in
the amphitheater of the Peter Bent Brigham Hospital on
Tuesday, March 13, at 8:15 p.m.

PROGRAM

Clinical case presentation from the Massachusetts General
Hospital.

Studies on Pleuropneumonia-Like Organisms in Human
Beings. Drs. L. Dienes, W. E. Smith, J. V. Meigs,
C. L. Parsons, and M. W. Ropes.

The Circulatory Action of Protovetratine. Dr. O. Krayser.
Studies with Venous Catheterization. Drs. L. Dexter,
C. S. Burwell, F. W. Haynes, and R. E. Seibel.

NEW ENGLAND PEDIATRIC SOCIETY

There will be a meeting of the New England Pediatric
Society on Wednesday, March 14. The case presentations
will be held in the Ether Dome, Bulfinch Building, Mas-
sachusetts General Hospital, and all other events at Long-
wood Towers, Brookline.

PROGRAM

4:00-5:30 Case Presentations: Pediatrics and Surgery by
the Children's Medical Service, Massachusetts
General Hospital.

6:30 Refreshments.

7:00 Dinner.

8:00 Annual meeting.

8:30 Newer Concepts in the Management of the
Newborn. Dr. Stewart H. Clifford.

NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting of the New England Roentgen Ray
Society will be held at the Harvard Club of Boston on Friday,
March 16. There will be an x-ray conference at 4:30 p.m.
At 8:00 p.m., the following program will be presented:

The Rectum and Sigmoid: New methods of roentgenologic
examination. Dr. George Levene.

The Rectum and Sigmoid: Surgical management of in-
flammatory and malignant lesions. Dr. Richard B.
Cattell.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

The regular meeting of the New England Society of Physical
Medicine will be held at the Hotel Kenmore, Boston, on
Wednesday, March 21, at 8 p.m. Mr. Kurt S. Lion will speak
on the topic, "The Physics of Short-Wave Therapy."

A council meeting will be held at 6:00 p.m., followed by
an informal dinner in the Empire Room at 6:30 p.m.

Members of the medical profession are cordially invited.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MARCH 15

FRIDAY, MARCH 16

*9:00-10:00 a.m. Proteolytic Enzymes in Tissues. Dr. Paul C.
Zamecnik. Joseph H. Pratt Diagnostic Hospital.

*9:00-10:00 a.m. Medical Clinic. Isolation Amphitheater, Chil-
dren's Hospital.

10:50 a.m. Bacterial Infections of the Skin. Dr. G. Schwartz. (Post-
graduate clinic in dermatology and syphilology.) Amphitheater,
Mallory Building, Boston City Hospital.

SATURDAY, MARCH 17

*10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham
Hospital.

MONDAY, MARCH 19

*12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent
Brigham Hospital.

TUESDAY, MARCH 20

*9:00-10:00 a.m. Medical Clinic. Infants' Hospital.

*12:15-1:15 p.m. Clinico-roentgenological conference. Peter Bent
Brigham Hospital.

WEDNESDAY, MARCH 21

*9:00-10:00 a.m. The Diagnosis of Diabetes Mellitus. Dr. Joseph
Rosenthal. Joseph H. Pratt Diagnostic Hospital.

*12:00 m. Clinicopathological conference. Children's Hospital.

*Open to the medical profession.

Incipient stage of the disease process is so frequently

associated with few or no symptoms; the presenting clinical picture often suggests another diagnosis; physical examination is notoriously unreliable because of the paucity or absence of physical signs; and the application of rigid diagnostic methods is often delayed because the physician has not developed a sufficiently strong suspicion of the underlying disease.

MISLEADING NATURE OF CLINICAL PICTURE

The early clinical course of intrathoracic lesions is apt to be misleading because symptoms are either absent or extremely mild or masquerade as some other disease process. The important clinical fact that physicians must come to recognize more fully is that there is almost always an early asymptomatic stage, during which the process can be discovered only by routine roentgenogram of the chest. When symptoms do occur, they usually point to disease in the chest, but they are apt to be so mild that the life-threatening cause is not suspected. As a result, many of these patients are treated for bronchitis, the common cold, grippe and so forth.

The masquerading character of carcinoma of the lung has been emphasized by Alexander² and Overholt.¹ Just how important a factor this is can be gleaned from the fact that 60 per cent of 153 patients studied by Overholt were treated on the basis of an incorrect diagnosis. These diagnoses included tuberculosis, unresolved pneumonia, lung abscess, bronchitis, asthma, heart disease, pleurisy, metastatic cancer and arthritis. Benign lung tumor may also present a similar bizarre clinical picture.

The masquerading character of pulmonary tuberculosis has not been so well described in the literature, but during the last few years I have seen tuberculosis simulate the clinical picture of bronchiectasis, abscess, asthma, pneumonia and carcinoma, as well as other less well defined clinical pictures, such as bronchitis and virus pneumonia. Recent bronchoscopic studies have revealed that 10 per cent of patients with pulmonary tuberculosis also have involvement of the major bronchi.³ As a result, stenosis is not infrequent and, like cancer, may cause all degrees of bronchial occlusion, with resulting obstructive emphysema, atelectasis and suppuration. Wheezing is a usual complaint of these patients, and they often seek advice because they believe that they have asthma. The wheezing, however, is always unilateral, and this should serve to differentiate it from true asthma.

Pleurisy, with or without effusion, spontaneous pneumothorax, persistent hoarseness or anal fistula may be the first condition of which the patient with pulmonary tuberculosis complains. All such patients should have chest roentgenograms to rule out pulmonary tuberculosis. In those with pleural effusion, the pleural fluid should be studied for tubercle bacilli by examination of a concentrated specimen, culture and guinea-pig inoculation. Be-

cause of the serious prognostic significance of pleural effusion, especially in young people, these patients should be treated as if they had parenchymal tuberculous lesions and followed routinely by frequent x-ray films of the chest. As Kallner⁴ found, 39 per cent of patients with pleural effusion who were denied sanatorium therapy developed pulmonary tuberculosis, usually within five years, and 22 per cent of these patients died. This is in striking contrast to the good prognosis of such patients when properly treated, as reported by Trudeau.⁵

No attempt will be made to cover completely the symptoms associated with intrathoracic diseases, but the following points require emphasis. Almost all the diseases of the chest have an early asymptomatic stage, during which the pathologic process can be discovered only by x-raying the chest. This stage is apt to be so mild that the seriousness of the underlying lesion is overlooked. The masquerading tendency of intrathoracic disease, especially cancer and tuberculosis, has been emphasized. They may masquerade as each other, or as any of the commonplace diseases of the chest, or as an entirely foreign clinical picture, such as arthritis.

UNRELIABILITY OF PHYSICAL EXAMINATION

Physical examination of the chest is an essential procedure in the evaluation of any patient, especially those with diseases of the chest. Relinquishment of such procedures is not advocated, but it must be emphasized that the time has come to recognize their limitations as well as their value. As early as 1933, Sampson and Brown⁶ reported that the staff of the Trudeau Sanatorium had concluded that moderately coarse rales at an apex were the only reliable data obtained on physical examination, and added that these were present in only 27 per cent of the minimal cases. They analyzed the occurrence of the five cardinal signs and symptoms of tuberculosis in a series of 280 cases with minimal disease. Tubercle bacilli were found in the sputum in 35 per cent, rales in 27 per cent, hemoptysis in 26 per cent, pleural effusion in 12 per cent, and x-ray evidence of pulmonary tuberculosis in more than 99 per cent. These pioneers pointed the way to the early diagnosis of pulmonary tuberculosis over a decade ago, yet in the everyday practice of the country and in the teaching of medical students methods of diagnosis are predominantly employed that cannot claim more than a 25 to 30 per cent efficiency. This partially explains why 85 to 90 per cent of patients with pulmonary tuberculosis are diagnosed only when they have reached the moderately advanced or far advanced stages.

In respect to carcinoma of the lung, physical signs are usually absent in the very early stages. Unilateral wheeze and suppression of breath sounds due to obstructive emphysema are the most frequent early signs. When bronchial obstruction is more complete, signs of atelectasis, consolidation or ab-

success may be present. It is only fair to state that physical signs are extremely unreliable and at best only suggestive in cases of pulmonary cancer.

VALUE OF ROUTINE FLUOROSCOPIC EXAMINATIONS

In 1927, the Metropolitan Life Insurance Company made fluoroscopic examination of the chest a routine supplement to each physical examination at its home office.^{7, 8} This enabled the examiners to discover intrathoracic abnormalities and disease that would have been missed by physical examination and history. As a result, treatment was started in the majority of cases before physical signs or symptoms had become apparent.

Block and Tucker⁹ recently reported to the American Trudeau Society their experiences with routine fluoroscopic examination of the chest of all patients admitted to the University of Chicago Clinic. The results of this admirable clinical study, which was applied to 15,000 cases, were remarkable. Positive findings were revealed in 3187 cases (21.3 per cent). The incidence of tuberculosis in this group of patients was 4.2 per cent, that of clinically significant tuberculous lesions 1.4 per cent, that of tumors of the lung 0.6 per cent, that of mediastinal and diaphragmatic disease 0.6 per cent, and that of cardiovascular disease 14.4 per cent. In addition, there were other significant findings, such as pleural disease, anomalies, skeletal disease, foreign bodies and subternal thyroid glands. The significant fact concerning the pulmonary tuberculosis discovered by this method was that two thirds of the patients had minimal lesions, one sixth moderately advanced, and one sixth far advanced lesions. This represents a reversal of the distribution of the stages of tuberculosis in patients referred from private practice to sanatoriums. On the basis of this study Block and Tucker estimate that in the fifteen years prior to the institution of routine chest fluoroscopic examination, 3000 cases of active tuberculosis were missed in their clinic in spite of careful history-taking and physical examination. They also state that in the coming year about 600,000 patients with pulmonary tuberculosis will undergo physical examination in hospitals and physicians' offices of this country without a diagnosis being established.

These data demonstrate the value of routine fluoroscopic examination of the chest as a supplement to the physical examination. They further show the inefficiency and inadequacy of the history and physical examination in apprehending intrathoracic abnormalities in the early stage of development.

VALUE OF ROUTINE ROENTGENOGRAMS

Stereoscopic 14-by-17-inch films remain the most ideal means of demonstrating lesions of the chest, but the prohibitive cost of this procedure, together with the demand for a cheaper and less cumbersome form of chest roentgenography for mass surveys,

has led to the development of miniature films taken by photofluorographic technique. The 35-mm. and 4-by-5-inch films are the ones in general use. Plain or stereoscopic views may be taken. Birkelo⁸ has demonstrated that the 4-by-5-inch film can be used in mass survey work with only a 2 per cent margin of error, as compared with results obtained with the regular 14-by-17-inch film.

The utilization of this technique in mass surveys has served to demonstrate that intrathoracic abnormalities, neoplasms and infections are much more frequent than has been assumed from available clinical or autopsy data. Under the direction of Hodges,¹⁰ of the University of Michigan Hospital, every patient admitted to the clinic since July 1, 1941, has had the benefit of a 35-mm. photofluorographic examination. Thorough roentgenologic study has been recommended for any patient whose miniature film reveals a significant abnormality. During the first four months of this work, 7841 patients were examined. Of these, 74.0 per cent had no abnormality, 14.1 per cent had deviations from normal not considered to be clinically significant, and 9.3 per cent had abnormalities demanding more extensive roentgenologic study. Hodges states, "Photofluorography employed to survey the chests of all patients regularly registered in hospitals and clinics can be expected to disclose signs of significant thoracic disease in 8 to 10 per cent of the patient group."

The foregoing data demonstrate conclusively that some form of roentgenologic study of the chest should be a routine procedure in the examination of every patient admitted to hospitals and institutions. Routine blood-cell counts reveal blood dyscrasias in a small fraction of 1 per cent of cases, routine urinalysis reveals diabetes in about 0.4 per cent, and routine serologic tests reveal syphilis in about 2 per cent. These routine laboratory procedures have been required for years in every good clinic and hospital. Yet, today, these same institutions are neglecting a procedure that will uncover 8 to 10 per cent significant thoracic disease. In the light of present knowledge, routine roentgenologic study of the chest is at least four times as efficient and important as any other routine procedure now in use. In addition to its value as a diagnostic aid, it serves to protect patients and the hospital personnel against the unsuspected active cases of tuberculosis that are constantly present in hospitals without any isolation technique whatsoever being applied. When either fluoroscopy or photofluorography is used, the procedure requires little time and can be done at a cost of only a few cents a patient. The additional expense can be defrayed by a minimal charge added to the laboratory fee.

VALUE OF SPUTUM STUDIES FOR TUBERCLE BACILLI

In every patient suspected of having tuberculosis careful sputum studies should be performed in an

attempt to confirm the diagnosis. A positive sputum, however, is not an absolute requirement for the diagnosis of pulmonary tuberculosis. A positive sputum may never be found in some patients with minimal lesions and in others with inactive disease.

Failure to secure positive results from sputum examination is often due to the fact that the technics applied are not sufficiently rigid. There are two important factors that determine the efficacy of sputum studies — the length of time over which the sputum specimen is collected and the method of examination. The routine smear for tubercle bacilli is notoriously unreliable. Twenty to 30 per cent of the sputums negative on direct smear are found to be positive when the sputum is examined by the concentration method. Pooled specimens, with the sputum collected over a period of three to seven days, further increases the positive findings. Multiple cultures and guinea-pig inoculation of the sputum and gastric contents should always be employed before one decides that the sputum is negative.

To avoid delay in diagnosis, the following routine is suggested. First, the use of routine smears should be avoided. These smears are so unreliable that a negative result is meaningless. Second, three consecutive seventy-two-hour pooled sputum specimens should be examined by the concentration method. If they are negative on microscopic examination, the sediment should be planted on a culture medium and inoculated into guinea pigs. Third, if the seventy-two-hour specimens are negative on microscopic examination, the next step is the immediate examination of three consecutive gastric lavages by the concentration method. Acid-fast bacilli are often found in gastric lavages when the sputum is negative, especially in children and young women. The gastric specimens should always be cultured and inoculated into a guinea pig to identify the acid-fast bacilli as tubercle bacilli.

Utilizing all available methods of examination, Pinner and Werner¹¹ have found that over 99 per cent of patients with active tuberculosis have tubercle bacilli in the sputum. Thus, when these tests are repeatedly negative in a patient with a demonstrable parenchymal infiltration in the lung that is apparently active, the lesion is probably non-tuberculous, and other diagnostic procedures are indicated.

DIAGNOSTIC PROCEDURES IN PATIENTS WITH SUSPECTED CANCER OF LUNG

Any patient with a visible tumor or an unexplained density or suppuration in the lung, especially if he is in the middle or older age group, should be suspected of having a pulmonary cancer. When such lesions are discovered in the minimal, asymptomatic stage, establishment of the diagnosis is most

urgent, because at this stage metastases and extension of the tumor are less likely to have occurred and surgical extirpation offers a greater chance of cure. Such patients should be bronchoscoped immediately; 60 to 70 per cent of bronchiogenic carcinomas originate in the major bronchi, and a biopsy specimen to establish the diagnosis can be obtained. All patients in whom the biopsy is positive should be explored at once, provided that no clinical evidence of metastasis or extension of the tumor is present.

If the bronchoscopy is negative, a bronchogram should be taken. At times this demonstrates an obstructing lesion in one of the smaller bronchi beyond the visual field of the bronchoscopist. A negative bronchogram, however, does not rule out a peripheral pulmonary malignant neoplasm. It is of value only when it gives positive results.

Surgical exploration of the chest is a safe procedure, and should be utilized more frequently to determine the etiology of unexplained pulmonary lesions. Physicians refer cases with unexplained abdominal disease for exploration without hesitancy, but for some unknown reason are extremely reluctant to refer patients for thoracic exploration. With modern operative technic, exploration of the chest can be performed with nearly the same degree of safety as an abdominal exploration, and with equally satisfactory results. The importance of early exploration is shown by the fact that it served to establish the diagnosis in 24 per cent of the 153 cases of carcinoma of the lung reported by Overholt.¹ This procedure should be used without delay in all cases with proved or suspected pulmonary or mediastinal tumors, unless evidence of metastasis or extension of the tumor is present or the age and general condition of the patient contraindicate an operative procedure.

Aspiration biopsy is used to secure tissue for pathologic study only in cases that are obviously inoperable. In patients in whom operation is possible, exploration is considered to be safer and more accurate.

DISCUSSION

Rienhoff¹² has admirably expressed the need for early diagnosis in cancer of the lung as follows: "Our clinical pace must be quickened, for until recently the great majority of recognized affections of the respiratory tract have been those in which Time was felt to be the Great Healer, but with the development of methods by which patients can not only be relieved, but cured of malignant neoplasm of the lung, it may be said that Time now takes on the role of executioner." The same idea can be applied to pulmonary tuberculosis and most of the other thoracic diseases. Almost without exception, the success of treatment is dependent on early diagnosis

and the prompt application of the indicated therapeutic measures.

Routine roentgenologic examination has been proved to be a valuable supplement, but should never be considered a substitute for a carefully taken history and a methodically performed physical examination. Occasionally, the history and physical examination point the way to the diagnosis when the roentgenogram reveals no definite abnormality. This is especially true of the early stages of bronchial disease, when the only symptom may be localized wheezing. It is also quite true of bronchiectasis, in which the presence of rales may first indicate the presence of the pathologic process.

The evidence already presented shows the value of routine roentgenologic study of the chest. This is particularly important in patients in whom the incidence of pulmonary disease, especially tuberculosis, is known to be high and the threat is known to be great, such as pregnant women and diabetic patients. The early diagnosis of pulmonary tuberculosis is important for pregnant women from the standpoint of giving proper care to the mother and adequate protection to her baby. It is important in diabetic patients because of the well-known fact that these two disease processes aggravate each other.

Another group of tuberculous patients are those in their late teens and young adults. Early diagnosis is more important here in any other age group because of the relatively poor prognosis and the tendency for the lesions to progress rapidly. Once a lesion is discovered in a patient in this age group, it should always be considered active until proved otherwise by careful clinical and x-ray follow-up. If it is active, immediate intensive therapy and prolonged bed rest are indicated. Roentgenograms of the chest should be taken at frequent intervals, sometimes as often as once a week. In such cases, tuberculosis is not a chronic disease but one that carries a great and an immediate threat to the patient.

The responsibility for the early apprehension of pulmonary disease rests largely on the shoulders of the general practitioner and the internist, since they are the first to see the patient. Their offices should and can be the greatest case-finding agencies in the entire field of medical practice. To make this possible, the limitations of the history, the physical examination and certain laboratory procedures must be more keenly appreciated, and more rigid diagnostic procedures must be applied routinely.

SUMMARY

Mass x-ray surveys have demonstrated that intrathoracic abnormalities, neoplasms and infections are much more frequent than has ever been suspected.

A series of illustrative case reports is appended.

ILLUSTRATIVE CASE REPORTS

CASE 1. J. M., a 44-year-old man, had for years had a chronic cough attributed to cigarette smoking. In March, 1942, he had blood-streaked sputum. A roentgenogram of the chest at that time showed infiltration in the right upper lobe that closely resembled a tuberculous lesion (Fig. 1A). The sputum was consistently negative. In spite of this, a

was performed. The patient made an uneventful recovery (Fig. 1D) and remained well until December, 1942, at which time he began to have low-grade fever and severe pain in the left lumbar area. He rapidly went downhill and died on February 22, 1943.

Pathologic examination of the surgical specimen revealed epidermoid carcinoma, Grade III, with metastasis to the bronchial lymph nodes. At the time of autopsy, metastases

C

D

FIGURE 1. Case 1.

diagnosis of pulmonary tuberculosis was made, and the patient was sent to Florida for a few months. During that time the cough persisted but the quantity of sputum became less. There was no weight loss.

During the 4-month period following the initial roentgenogram, the shadow in the right upper lobe became quite dense and rapidly enlarged (Fig. 1B and C). A diagnosis of tumor was made and the patient was referred for surgery in August, 1942, about 5 months after the first roentgenogram of the chest. Bronchoscopy was negative. Exploratory thoracotomy was immediately performed. At operation a huge tumor mass was found in the right upper lobe. No mediastinal lymph nodes were palpable. A pneumonectomy

were found in the spleen, the left adrenal gland and the peritracheal and supraclavicular lymph nodes.

Comment. This case demonstrates carcinoma of the lung masquerading as pulmonary tuberculosis in its early stages. The persistently negative sputum should have indicated further diagnostic procedures. An exploratory thoracotomy at the time of the first roentgenogram would have settled the diagnosis, and pneumonectomy at that time would have offered a better chance of cure.

CASE 2. G. B., a 51-year-old man, became ill in February, 1943, at which time he was treated for "grippe." He never felt well following this, and mild cough and expectoration

continued. In July, blood streaking of the sputum first occurred. This reoccurred on several occasions. Roentgenograms revealed infiltration in the left lower lobe. There had been a weight loss of 20 pounds. The patient was treated for unresolved pneumonia. He was first seen in consultation in April 4, 1944, at which time his general condition was good and there was no evidence of further metastasis. Pathologic examination revealed a 4-by-4-cm. tumor in the lower lobe. Beyond the tumor, the lung was atelectatic and the bronchi were dilated.

FIGURE 2. Case 2.

Comment. This case illustrates bronchogenic carcinoma presenting the clinical picture of grippe at its onset. The first roentgenogram of the chest was not taken until 6 months after the onset of symptoms, and the patient was not referred for surgical treatment for another 4 months. A roentgenolobe (Fig. 2*B*). Bronchoscopy was negative. Exploratory lateral view showed the opacity to lie posteriorly in the lower an opacity adjacent to the left border of the heart. The roentgenogram (Fig. 2*A*) revealed December, 1943, about 10 months after the onset of symptoms. At that time, the roentgenogram (Fig. 2*A*) revealed

FIGURE 3. Case 3.

thoracotomy was performed and a tumor mass (epidermoid, Grade II) was found in the lower lobe, which had extended into the mediastinum around the inferior pulmonary vein. A palliative pneumonectomy was performed. X-ray therapy was used postoperatively. The patient was last seen on Case 3. D. M., a 26-year-old, married diabetic woman, had a chest roentgenogram in 1931 that revealed a small scar

in the apex of the right lung. The patient was not instructed to have frequent x-ray check-ups. The next film was taken in February, 1941, and an infiltration was found in the right apex. A checkup was advised in 2 months' time. The patient failed to return, and the next roentgenogram was taken in October, 1942 (Fig 3A). At that time there was an exudative

the diagnosis and also in evaluating the course of the disease process.

CASE 4. V. S., a 51-year-old, married woman, had an acute illness in May, 1943, and was told that she had pneumonia. Following the acute episode she failed to regain her strength,

FIGURE 4. Case 4.

lesion at the right apex but no visible cavity. The patient was asymptomatic, and there were no physical signs. Crushing of the right phrenic nerve was performed, and the patient was placed on bed rest.

During the following year, x-ray films showed progressive retrogression of the lesion at the right apex, and the patient

and cough and expectoration became progressively worse. She was first seen in consultation in August, 1943, at which time the outstanding symptoms were marked cough, expectoration of 8 to 10 cc. of mucopurulent sputum daily and wheezing in the left side of the chest. A roentgenogram of the chest (Fig 4A) revealed a dense opacity in the midzone of the left lung adjacent to the hilus. The patient's age, the clinical picture and the roentgenogram all pointed to a diagnosis of bronchiogenic carcinoma. This was especially true because the sputum had been consistently negative on repeated examination by the concentration method. Bronchoscopy revealed edema and thickening of the mucosa throughout the left bronchial tree. The mucosa was also slightly inflamed and granular in appearance. No evidence of tumor was found. Bronchoscopy indicated that the process was probably due to tuberculosis. A few weeks later the sputum was proved by culture to be positive for tubercle bacilli.

The patient has been followed by bronchoscopy since then. The process extended into the trachea and eventually ulcerated. The upper portion of the right main bronchus also became involved. In October, 1943, atelectasis of the right upper lobe occurred; it disappeared within a few weeks (Fig. 4B). In recent months the patient has improved, the ulceration in the bronchus has disappeared, and the infiltration in the left lung has cleared slightly. There is now, however, a suspicious cavity in the apex of the left lower lobe (Fig. 4C).

Comment. This case illustrates tuberculosis masquerading as cancer of the lung. It also demonstrates the importance of rigid study of the sputum before deciding that it is negative. Bronchoscopy was helpful in establishing the diagnosis.

FIGURE 5. Case 5.

remained asymptomatic. She was x-rayed every 3 months during this time. In January, 1944, a roentgenographic check-up revealed a definite spread of the lesion (Fig. 3B). The patient still had no symptoms, and the physical examination was entirely negative.

Comment. This case illustrates a silent tuberculous lesion occurring in a young diabetic patient. It demonstrates the inadequacy of the history and physical signs in establishing

CASE 5. F.R., a 55-year-old man, "caught cold" 8 weeks prior to the time he was referred for treatment. This illness subsided, and he felt well. One month later he had several hemoptyses, a low-grade fever and some malaise and had lost 15 pounds. A roentgenogram of his chest taken at the first examination on June 16, 1943, showed density in the region of left hilus (Fig. 5). Bronchoscopy was negative, and bronchograms revealed no abnormality. Exploratory thoracotomy was performed and a small tumor was found in the left upper-lobe bronchus. Pneumonectomy was performed. The patient is asymptomatic and well.

Pathologic examination of the surgical specimen showed a small Grade III epidermoid carcinoma in the left upper lobe bronchus. All the lymph nodes were normal.

Comment. Only 8 weeks intervened between the onset of symptoms and the time at which definitive surgical treatment was performed. This case shows the value of early explora-

tory thoracotomy in establishing the diagnosis and thus affording a good chance of cure.

Cases 6, 7, 8 and 9. These 4 patients had intrathoracic lesions that produced absolutely no symptoms. In all the diagnoses were made by routine roentgenograms of the chest.

gram of the chest taken two years previously. Figure 6C shows the roentgenogram of a 20-year-old man (Case 8) with a huge mediastinal tumor, which proved to be an adenocarcinoma; this was discovered while the patient was on active duty in the Marine Corps. Figure 6D shows the roentgenogram of a 23-year-old man (Case 9) with moderately

FIGURE 6. Cases 6, 7, 8 and 9.

C

Figure 6A shows the chest roentgenogram of a 16-year-old boy (Case 6) with a diaphragmatic hernia, which was discovered in a school survey. Figure 6B shows the chest roentgenogram of a 23-year-old student nurse (Case 7) with a mediastinal cyst into which hemorrhage had occurred; physical examination was negative, as well as a roentgenographic examination. The patient is under control with pneumothorax.

advanced pulmonary tuberculosis involving the left upper lobe; there was a 3-cm. cavity at the level of the anterior second rib, without physical signs or symptoms. The first three patients have been operated on successfully and are in perfect health; the tuberculosis of the last patient is under

CHALLENGES TO MEDICINE*

VICTOR JOHNSON, M.D.†

CHICAGO

THROUGHOUT the country, many hundreds of medical students are graduating this month. Nearly all of them automatically become Army and Navy officers, scheduled to be assigned to duty in the jungles of Burma, the deserts of Africa, the snows of Alaska, the mountains of the Balkans or the interior of Germany or Japan. They, and you, can embark for duty in a far corner of the earth supremely confident in yourselves, and your complete competence to meet every situation.

If your medical education has been hastened, remember that the accelerated program has already provided new medical officers for many thousands of our fighting forces. If your classes have been crowded, know that there will be fewer doctors for the civilian population after the war than before the war, despite acceleration and increased enrollments. If your teachers have been reduced in numbers, be sure your medical education is still far superior to that obtainable anywhere in the world, even in peacetime. If you have been beset from day to day with numberless uncertainties, recall that you share doubts with the entire civilized world.

We have supreme confidence in you, in your ability to discharge your obligations not only in this great conflict, but in the equally difficult readjustments to be made after the war.

Medical students, medical faculties, medical scientists — all of American medicine — may well hold their heads high in any accounting that is held of contributions to winning the war. Thousands of men who would have died in the last war will return to useful and happy lives because of plasma, penicillin, surgery, air evacuation of the wounded and because of the medical officers — because of you. We know that as you have met your responsibilities in the past you will carry on the proud tradition of service in the immediate future during this conflict, and we know that you will likewise accept with resolution the challenges of the future in the world of peace, which will even transcend in importance the tasks of today. The problems to be met are those of education, adjustment to civilian life and expansion of the effectiveness of medicine in a changing world.

EDUCATION

The last war was won by food. "Food will win the war." It was won by the United States, with her fresh, strong forces. The war was won by the

French holding fast before Paris, by the British blockade of Germany, by the defection of the German people, by the German sailors at Kronstadt, by the American skilled worker — by everyone who participated.

This war will see fewer such credit lines. Perhaps we have become mature. German is still taught in our colleges, and many medical schools still require it for admission. Wagner still fires the pulse, and we continue to trust Goethe, who could say to a world less sick than ours, "Thou ailest here, and here, and here."

We have reached maturity, perhaps, and we shall not say, "Brains won the war, education won the war." Education has done its stint. Colleges, universities and professional schools have made available their entire educational resources, and many many thousands of men will be better citizens in peacetime for the education they received for war.

I need not recount to you the many Army Specialized Training and Navy programs. You are familiar with the numerous projects in operation: radar and radiography; parachute physiology and parasite detection; planes and plasma.

Education for war has been universal, but the education of soldiers for peace has also taken place. The Armed Forces Institute offers correspondence courses in any subject and at every level, to every soldier or sailor with leisure for study. An educational project under the Army Education Branch is planning to serve the demands and intellectual curiosities of thousands of soldiers in the interim between the surrender of Germany and that of Japan. It is anticipated that many thousands of men will spend weeks to months in Europe before the crowded transport facilities of that time will be able to carry away the last of our armies to America or the Pacific. How can that time be most profitably utilized? For many, it will be a period of formal organized education. Scores of courses are now being developed in all the fields of learning, from the level of the high school to advanced university work. Textbooks have been selected and outlines prepared for courses varying from one to several months. Wherever possible, physical educational facilities in Europe will be used, including the modest school buildings of the small cities and the laboratories of the great universities. The instructors will come from the officers and men. Here a private who has had a year of college will give instruction in high school biology; there a Ph.D. will give college instruction.

Some of the educational projects and programs of this war approach the fantastic. Vice-Admiral Ross

*Convocation address, delivered at Boston University School of Medicine, Boston, September 22, 1944.

†Secretary, Council on Medical Education and Hospitals, American Medical Association; professorial lecturer in physiology, University of Chicago.

We already know something of the magnitude of the problem. It is now nearly two years since the Council on Medical Education and Hospitals of the American Medical Association anticipated the problem to be faced, and set about to meet it, collaborating with hospitals, American boards in the specialties, medical schools and, most recently, the Committee on Postwar Medical Services. This committee was established by the American Medical Association, in collaboration with the American College of Physicians and the American College of Surgeons. Representation is also included from the Association of American Medical Colleges, the American Hospital Association, the Federation of State Licensing Boards of the United States, the Catholic Hospital Association, the Procurement and Assignment Service, the Advisory Board for Medical Specialties and the Veterans Administration. A major project of this committee has been a study of the postwar educational desires of medical officers, which is being conducted in co-operation with the surgeons general of the Army, Navy and Public Health Service. Questionnaires on the postwar educational desires of medical officers have been sent to all physicians in all branches of the Service. Returns are now being received at the American Medical Association headquarters in great numbers. Transferred to punch cards, this information will be systematically analyzed and given wide publicity, so that each state medical society, each medical school and each hospital will be made aware of its responsibilities.

Analyses of the first 1000 returns have been published by Lieutenant Colonel Harold C. Luchatz and the Council on Medical Education and Hospitals.³ The report of the Council indicates that considerable expansion is required in providing facilities in all fields, and for periods ranging from several weeks in refresher and review courses to many months in internships and residencies. Of the 1000 officers, about 20 per cent indicated that they planned no further postwar training. Eighty per cent—mainly younger officers—desired some additional education. About one third of those who replied desired six months or less of training, and nearly half desired hospital training of six months or more.

To meet the requirements of returning medical officers for additional training is a serious responsibility that will require the continued joint efforts of the Committee on Postwar Medical Service, the Council on Medical Education and Hospitals, the surgeons general of the Army, Navy and Public Health Service, hospitals approved for internships and residencies, the American boards in the medical specialties, medical schools, state licensing boards, the Veterans Administration, foundations, county and state medical societies and every institution capable of providing advanced training to physicians.

McIntire, Surgeon General of the Navy, tells of clinics held in midocean. In a convoy not in trouble, or in a task force on a long journey, the medical officers in the many vessels of the fleet meet at a stated time on one of the larger vessels. Here are assembled, under the direction of competent medical officers of higher rank, selected cases of general interest and stubborn diagnostic problems encountered in any large body of men subject to illness or injury. A clinic is held, especially for the instruction of the younger officers whose hospital training has been curtailed. This is medical education that may be characterized as unconventional, at least.

At the University of Edinburgh, in Scotland, an event unique in medical annals is occurring. When Poland was overrun, thousands of Polish officers and men and civilians were evacuated to England. Many of these had been medical students. Among the medical officers were a goodly number of teachers from the Polish medical schools. The University of Edinburgh provided classroom, laboratory and clinic facilities, and there was set up the first medical school in the history of any country in which citizens of the country taught their fellowmen in their own tongue in a foreign land. The Polish Medical School of Edinburgh has graduated two classes of future Polish doctors, and has made a respectable contribution in research. This amazing experiment in international medicine will yield incalculable dividends in the rebirth of medicine and education in Poland, which the Germans boast has now been reduced to an intellectual desert.

In the midst of our efforts here at home to produce competent medical officers at the maximum rate, consistent with high quality, we are deeply concerned with your future continuation training. Despite the wartime educational efforts mentioned, we may be sure that when the balance is struck, the debits will far outweigh the credits, in all fields of education. In medicine, this will be reflected in a lower quality of medical care after the war, unless the challenge is met resolutely and wisely.

Recent graduates are keenly aware of their deficiencies. They have been compelled to complete their training under unfavorable conditions. Teaching staffs have been depleted while their teaching loads have been increased and the tempo of education hastened. The internship has been necessarily reduced to an inadequate nine months, a period barely sufficient to make the discerning student aware of the medical problems he will face in the practice of medicine but utterly insufficient to do more than start him on the way to their solution. Medical educators are likewise keenly aware of the necessity for providing, after the war, continuation courses and advanced hospital training not only for new generations of medical graduates but for the returning medical officers as well.

CHALLENGES TO MEDICINE*

VICTOR JOHNSON, M.D.†

CHICAGO

THROUGHOUT the country, many hundreds of medical students are graduating this month. Nearly all of them automatically become Army and Navy officers, scheduled to be assigned to duty in the jungles of Burma, the deserts of Africa, the snows of Alaska, the mountains of the Balkans or the interior of Germany or Japan. They, and you, can embark for duty in a far corner of the earth supremely confident in yourselves, and your complete competence to meet every situation.

If your medical education has been hastened, remember that the accelerated program has already provided new medical officers for many thousands of our fighting forces. If your classes have been crowded, know that there will be fewer doctors for the civilian population after the war than before the war, despite acceleration and increased enrollments. If your teachers have been reduced in numbers, be sure your medical education is still far superior to that obtainable anywhere in the world, even in peacetime. If you have been beset from day to day with numberless uncertainties, recall that you share doubts with the entire civilized world.

We have supreme confidence in you, in your ability to discharge your obligations not only in this great conflict, but in the equally difficult readjustments to be made after the war.

Medical students, medical faculties, medical scientists — all of American medicine — may well hold their heads high in any accounting that is held of contributions to winning the war. Thousands of men who would have died in the last war will return to useful and happy lives because of plasma, penicillin, surgery, air evacuation of the wounded and because of the medical officers — because of you. We know that as you have met your responsibilities in the past you will carry on the proud tradition of service in the immediate future during this conflict, and we know that you will likewise accept with resolution the challenges of the future in the world of peace, which will even transcend in importance the tasks of today. The problems to be met are those of education, adjustment to civilian life and expansion of the effectiveness of medicine in a changing world.

EDUCATION

The last war was won by food. "Food will win the war." It was won by the United States, with her fresh, strong forces. The war was won by the

French holding fast before Paris, by the British blockade of Germany, by the defection of the German people, by the German sailors at Kronstadt, by the American skilled worker — by everyone who participated.

This war will see fewer such credit lines. Perhaps we have become mature. German is still taught in our colleges, and many medical schools still require it for admission. Wagner still fires the pulse, and we continue to trust Goethe, who could say to a world less sick than ours, "Thou ailest here, and here, and here."

We have reached maturity, perhaps, and we shall not say, "Brains won the war, education won the war." Education has done its stint. Colleges, universities and professional schools have made available their entire educational resources, and many many thousands of men will be better citizens in peacetime for the education they received for war.

I need not recount to you the many Army Specialized Training and Navy programs. You are familiar with the numerous projects in operation: radar and radiography; parachute physiology and parasite detection; planes and plasma.

Education for war has been universal, but the education of soldiers for peace has also taken place. The Armed Forces Institute offers correspondence courses in any subject and at every level, to every soldier or sailor with leisure for study. An educational project under the Army Education Branch is planning to serve the demands and intellectual curiosities of thousands of soldiers in the interim between the surrender of Germany and that of Japan. It is anticipated that many thousands of men will spend weeks to months in Europe, before the crowded transport facilities of that time will be able to carry away the last of our armies to America or the Pacific. How can that time be most profitably utilized? For many, it will be a period of formal organized education. Scores of courses are now being developed in all the fields of learning, from the level of the high school to advanced university work. Textbooks have been selected and outlines prepared for courses varying from one to several months. Wherever possible, physical educational facilities in Europe will be used, including the modest school buildings of the small cities and the laboratories of the great universities. The instructors will come from the officers and men. Here a private who has had a year of college will give instruction in high school biology; there a Ph.D. will give college instruction.

Some of the educational projects and programs of this war approach the fantastic. Vice-Admiral Ross

*Convocation address, delivered at Boston University School of Medicine, Boston, September 22, 1944.

†Secretary, Council on Medical Education and Hospitals, American Medical Association; professorial lecturer in physiology, University of Chicago.

McIntire, Surgeon General of the Navy, tells of clinics held in midocean. In a convoy not in trouble, or in a task force on a long journey, the medical officers in the many vessels of the fleet meet at a stated time on one of the larger vessels. Here are assembled, under the direction of competent medical officers of higher rank, selected cases of general interest and stubborn diagnostic problems encountered in any large body of men subject to illness or injury. A clinic is held, especially for the instruction of the younger officers whose hospital training has been curtailed. This is medical education that may be characterized as unconventional, at least.

At the University of Edinburgh, in Scotland, an event unique in medical annals is occurring. When Poland was overrun, thousands of Polish officers and men and civilians were evacuated to England. Many of these had been medical students. Among the medical officers were a goodly number of teachers from the Polish medical schools. The University of Edinburgh provided classroom, laboratory and clinic facilities, and there was set up the first medical school in the history of any country in which citizens of the country taught their fellowmen in their own tongue in a foreign land. The Polish Medical School of Edinburgh has graduated two classes of future Polish doctors, and has made a respectable contribution in research. This amazing experiment in international medicine will yield incalculable dividends in the rebirth of medicine and education in Poland, which the Germans boast has now been reduced to an intellectual desert.

In the midst of our efforts here at home to produce competent medical officers at the maximum rate, consistent with your future continuation training. Despite the wartime educational efforts mentioned, we may be sure that when the balance is struck, the debts will far outweigh the credits, in all fields of education. In medicine, this will be reflected in a lower quality of medical care after the war, unless the challenge is met resolutely and wisely. Recent graduates are keenly aware of their deficiencies. They have been compelled to complete their training under unfavorable conditions. Teaching staffs have been depleted while their teaching loads have been increased and the tempo of education hastened. The internship has been necessarily reduced to an inadequate nine months, a period barely sufficient to make the discerning student aware of the medical problems he will face in the practice of medicine but utterly insufficient to do more than start him on the way to their solution. Medical educators are likewise keenly aware of the necessity for providing, after the war, continuation courses and advanced hospital training not only for new generations of medical graduates but for the returning medical officers as well.

We already know something of the magnitude of the problem. It is now nearly two years since the Council on Medical Education and Hospitals of the American Medical Association anticipated the problem to be faced, and set about to meet it, collaborating with hospitals, American boards in the specialties, medical schools and, most recently, the Committee on Postwar Medical Services. This committee was established by the American Medical Association, in collaboration with the American College of Physicians and the American College of Surgeons. Representation is also included from the Association of American Medical Colleges, the American Hospital Association, the Federation of State Licensing Boards of the United States, the Catholic Hospital Association, the Procurement and Assignment Service, the Advisory Board for Medical Specialties and the Veterans Administration. A major project of this committee has been a study of the postwar educational desires of medical officers, which is being conducted in co-operation with the surgeons general of the Army, Navy and Public Health Service. Questionnaires on the postwar educational desires of medical officers have been sent to all physicians in all branches of the Service. Returns are now being received at the American Medical Association headquarters in great numbers. Transferred to punch cards, this information will be systematically analyzed and given wide publicity, so that each state medical society, each medical school and each hospital will be made aware of its responsibilities. Analyses of the first 1000 returns have been published by Lieutenant Colonel Harold C. Luehr, and the Council on Medical Education and Hospitals.³ The report of the Council indicates that considerable expansion is required in providing facilities in all fields, and for periods ranging from several weeks in refresher and review courses to many months in internships and residencies. Of the 1000 officers, about 20 per cent indicated that they planned no further postwar training. Eighty per cent—mainly younger officers—desired some additional education. About one third of those who replied desired six months or less of training, and nearly half desired hospital training of six months or more.

To meet the requirements of returning medical officers for additional training is a serious responsibility that will require the continued joint efforts of the Committee on Postwar Medical Service, the Council on Medical Education and Hospitals, the surgeons general of the Army, Navy and Public Health Service, hospitals approved for internships and residencies, the American boards in the medical specialties, medical schools, state licensing boards, the Veterans Administration, foundations, county and state medical societies and every institution capable of providing advanced training to physicians.

On the basis of the estimated demands for educational opportunities, the Council on Medical Education and Hospitals of the American Medical Association is already engaged in a ten-point program aimed at filling these needs. Internships, residencies, fellowships, graduate externships, and review and refresher courses are being developed to meet these needs. This is a solemn obligation we owe to the young physician now at war, who has given so much, so freely and so well. But there is also the added obligation to ensure that a high quality of medical care will be maintained in this country, lest the health of the Nation should suffer for years to come. You who graduate today may count on us who lay these plans to do our utmost for your continuation training after the war.

ADJUSTMENT TO CIVILIAN LIFE

Those of you who remember Remarque's great novel of the last war, *All Quiet on the Western Front* will recall with deeper feeling his novel of the peace that followed, *The Road Back*. War still poisoned the returned German soldier, even in the green meadows and wooded hills of his childhood. Here he did not relive the games of school picnics but, crouching behind a tree, noted at once what a perfect defense could be made there. He saw on that hill an artillery battery, and in that grove two machine-gun nests. There were snipers in the shrubbery. There was a perfect trap, with withering crossfire.

We escaped the Hun hatred of the last war that included an unreasonable hatred of German literature and music. Perhaps we shall be sufficiently civilized also to avoid the psychologic perils of the coming peace. Perhaps Remarque's character will be supplanted with the young infantryman I recently met on a train from the South. He was en route to Fort Sheridan to be discharged. The "fruit salad" on his left chest included three combat stars. I said: "Well, the war is over for you. And now what will you do?" He chuckled his response: "I'm going back to the farm. I'll rest awhile, maybe two weeks, with breakfast in bed every morning. Then I'll go to work. We have a fine farm. We raise corn and hogs."

Every returning soldier will face his own peculiar problem in his adjustment from a life of hardship where every decision was made for him to a life less hard but requiring him to do the deciding. Medical officers will face their own special problems.

When the war ends, thousands of physicians will have known no other form of medical practice than that of completely socialized medicine. The group practice of medicine is not socialized medicine. Neither is salaried medical practice, or hospital or sickness insurance. Socialized medicine is a system in which all doctors are paid from tax moneys, no patient pays his doctor directly, and all patients are provided with free medical care. This form of

practice is necessarily the rule in the armed forces. Army and Navy medicine is completely socialized, and is the form of practice of one third of the active physicians of the United States today.

In the armed forces, everyone who needs medical care must get it. The economic status of the patient is never even considered. The only criterion for the best of treatment is the need of the patient. Every resource of medical science must be employed when available and indicated: plasma or penicillin, surgery or psychiatry, regardless of cost. No obstacle can be too great to surmount, whether it may require eight natives to carry a single wounded soldier to a medical station in the Owen Stanley Mountains, or a fleet of air transports to carry the injured from the fields of France to a hospital in England.

There is no doubt that wartime experiences of physicians and of patients will stimulate increased efforts toward the provision of improved medical care for everyone, but without that necessary total regimentation that must obtain in the armed forces. Such regimentation is complete, in every phase of the life of both the doctor and the patient. The patient is ordered to appear before the doctor, and the doctor in turn may order the patient to the hospital. This has not been possible in civilian life. It is very disturbing to everyone who is interested in providing the best medical care for everyone to examine certain hospital statistics in this country. If the various states are arranged in the order of number of available hospital beds per 1000 people, it is seen that the same order is followed in the percentages of those beds that are occupied. But the correlation is the reverse of what we should expect. In general, those states having the fewest hospital beds have the lowest rates of occupancy of those beds. States with most beds use them most.

Why this is true we do not know. It may be that in those states that lack the money for hospital beds the people lack the money to use them. It may be that some of these hospitals do not provide a high grade of medical care. It may also be that the people do not sufficiently demand medical care even when it is available, because of ignorance, superstition, prejudice or sheer inertia. Even among the more fortunate classes of people, full use is not made of available medical facilities. I dare say that virtually everyone here would subscribe to the principle of an annual physical examination for everyone. Yet extremely few seek such examinations, even in normal times, unless compelled by an insurance, employment or other requirement, or unless frank illness sets in.

The demand for medical care in civilian life is different from the need for it. One of our major goals must be educational: to inform people of the facilities available and the necessity for using them. Such a program of education of the public for the prevention of disease should center about the hos-

become twofold: the training of medical graduates and the informing of the public.

These considerations, these consequences of war and the practice of medicine in the armed forces, carry us to the third of the major challenges that must be met by the medicine of tomorrow.

EXPANDING THE EFFECTIVENESS OF MEDICINE

The drives that have carried American medicine to its present high position will continue, and will carry it far beyond the present frontiers of service to mankind. The first of these undeniable urges is the spirit of scientific inquiry. It made Von Döbering and Alinkowski wonder why their operated dogs voided urine containing sugar, and it kept Banting and Best from quitting when their first experiments on diabetic dogs were inconclusive. It gave the world insulin.

This urge impelled Whipple to try empirically all the edibles that occurred to him in the treatment of dogs he had made anemic, and it stimulated Alnot and Murphy to extend the observations to human beings. And today, we have the liver treatment of pernicious anemia.

But though we can now control these formerly fatal disorders, we still do not know their basic cause. We cannot prevent them, and when treatment is suspended, the diabetic or the pernicious anemia patient is as seriously ill as ever. The first causes are still unknown and uncontrollable. The successes of the past provide ample hope, however, that this challenge will also be met, not only in diabetes and pernicious anemia but in hypertension, infantile paralysis and cancer, as well as in meeting the problems of a more equitable distribution of medical care.

Scientific experimentation not only must provide the solution of the problems of control of disease but also must guide us in determining the forms that medical practice shall take in the future. Medical science plans experiments, measures results and plans further experiments, to the end of greater and greater understanding of man in health and disease. This same spirit must direct us in solving the equally complex problems of man's relation to his fellows and the place of medicine in a changing social and economic structure.

Changes will come. You will be involved in them. In part, you will direct them. In so far as you exert influence, you should be impelled by the impartial spirit of inquiry that served you so well in your pursuit of the truth in the medical sciences.

We must recognize the extreme complexity of the problem. To state that doctors are attracted to cities because they can make more money there is a gross oversimplification. Cities provide the essential tools for the practice of medicine, which have been many times multiplied — x-ray equip-

ment, electrocardiographs, other laboratory facilities, consultation services and, above all, hospitals. The economic level in many rural communities, and in many counties in the United States, makes it impossible for those communities, unaided, to provide either doctors or the necessary facilities for doctors to carry on their work. It seems clear that hospital facilities will be lacking or will remain at a substandard level in many rural communities in the United States unless there is increased state and federal aid for hospital construction and equipment, the organization of clinics and the development of traveling clinics, to be operated under local control.

But even if all this were provided for the country physician, problems of distribution of medical care would remain. The doctor demands, in common with his civilized fellows, a life with stimulating social, intellectual and cultural contacts. Good schools, homes, churches, music and comradeship may loom as large in his selection of a community to practice in as income, x-ray facilities or hospitals. The distribution of medical care is only one aspect of the larger problem of elevating the general economic level of large numbers of our population in peacetime. If unemployment is kept as low as now, and production is maintained at the present level after the war and dedicated to the welfare of the people, the problems of distribution of medical care will be greatly diminished.

Difficult though these problems are, they must be attacked. Here, as in science, experimentation provides the most promising approach. New experiments are being planned almost daily, and the reports are rapidly accumulating. The California Physicians Service, under the auspices of the San Francisco County Medical Society, is rapidly increasing the scope of its services. About a year ago, the rate of growth of the Service was about 1000 new members a month. Today, 6000 members a month are being added, although the net gains are less than these figures indicate because of the turnover in employment.

The Prepaid Medical Service in Connecticut is operating on a cash-indemnity basis under the auspices of the Connecticut State Medical Society. The Committee on Medical Economics of the Kansas Medical Society is developing a prepayment plan for certain medical services. In Michigan it is reported that one person in nine is covered by Michigan Medical Service certificates, and one in five by those of Michigan Hospital Service.¹

The Missouri State Medical Association has unanimously adopted a plan of prepayment for medical and surgical care in hospitals, to be known as Missouri Medical Service, Inc.

In Nebraska, the House of Delegates of the Nebraska State Medical Society has adopted a resolution providing for the study of insurance plans and organization of such a plan for Nebraska.

Numerous other plans have been in operation, for varying periods, on a statewide or county basis, under the auspices of the medical profession. This is true in Colorado, Massachusetts, New Jersey, New York, Pennsylvania, Utah, Texas, Kansas, Delaware and North Carolina. These plans must be looked on as experiments in the more complete and equitable distribution of medical care.

As in the fields of the more exact sciences, these experiments in medical sociology are likely to turn out to be poorly conceived, in some instances, and often the results may be difficult to interpret. But the all-important fact remains: experiments in the distribution of medical care are in progress, and we may hope that they will be as fruitful as those that provided insulin for diabetes, liver for pernicious anemia and penicillin for infections.

We are impelled to continue experiments of this kind, as well as experiments in carrying patients to the doctors with adequate modern facilities, recalling the air transport of the wounded in battle, instead of struggling to provide doctors and hospitals for every community. We must experiment with traveling clinics and the closer integration of diagnostic, hospital and expert consultation services. Above all, we must experiment rather than design blueprints in the skies; we must follow the methods of science, not the promptings of the emotions.

* * *

You who are graduating are heirs to a glorious heritage of the past. And you face a challenge unequaled in the past. We will afford every help in

the furtherance of your educational aims. We will assist you in your adjustment to civilian practice. And we enlist your enthusiastic endeavors to make the art and science of medicine, which you have so well learned, available to all who need it.

We know that you will serve your fellows selflessly. Despite your trials, you, and all of us who have remained at home, have little justification for complaint. All of us here owe so much to our friends and allies. A recent medical graduate in Britain⁵ has put it well:

It is hard for my immediate generation to forget that their services have been paid for already, by the bodies of men no stronger and brains no less trained. It is difficult to say that we deserved it, even when it was part of a well-laid, state-planned calculation. We were reserved, held out of the line, while Jock (who was trained as a diplomat) took his platoon behind the enemy lines to destroy thirty-six aeroplanes and was killed by a bleeding artery on the way home; and Michael died when he led his company on to the last objective at El Alamein (he had passed his final examination before ordination); and Melvin bombed the dam when he could have stayed comfortably in the RAF in America. If such people had not given up their jobs and gone to war we should not be doctors now. It is my salutary misfortune to remember how much they entertained the world without trying, and helped the world without the special equipment of medicine.

MEDICAL PROGRESS

INSECT VECTORS OF DISEASE

VLADO A. GETTING, M.D., DR.P.H.*

BOSTON

SINCE December 7, 1941, all Americans have become conscious of war—for Japan had suddenly burst America's bubble of isolationism. Although many persons considered the United States as self-sufficient and apart from the rest of the world, and therefore safe from the conflagration of war, public-health officials, however, have been deeply concerned, fearful of the involvement of the country in a global war, with its inevitable rise in infectious diseases and death. Since time immemorial, wars have been attended by pestilence and death.

Under war conditions, many of the safeguards of the health of both the military and civilian populations are abandoned. The crowding of people, the primitive environmental conditions and the lack of personal hygiene are all conducive to the spread of infectious disease. The concentration and movement of large groups of population—civilian and military—and the limitless hardships, with fatigue, general malnutrition, famine and exposure, and the lack of medical care experienced by civilians and some armies, provide the fuses for the explosion of epidemics.

More soldiers have invariably been killed by infectious disease than by bullets in all wars prior to the Franco-Russian War of 1870, when the German Army reported an excess of deaths from battle.¹ In the Russo-Japanese War of 1904, both sides maintained the high proportion of deaths from wounds. In spite of the toll of influenza, the American Expeditionary Forces of 1917-1918 reported fewer deaths from sickness than from battle; although for the entire United States Army, at home and abroad, the deaths from disease were more numerous. During and after World War I the usual war diseases were highly prevalent in eastern Europe.² There was an epidemic of typhus fever throughout Russia, Poland and Serbia. Fortunately, the disease did not spread to western Europe. Malaria was victor in Macedonia and decimated the opposing armies to a tragic ineffective fraction.³ Although it had previously disappeared from most of Europe,⁴ malaria returned with the soldiers and evacuees to central, eastern and northern Europe to ravage the population. The United States Army, fortunately, escaped any extensive involvement of insect-borne disease, as the zone of military operations did not extend into areas where these diseases were endemic.

This global war is much more hazardous to civilian health than any in history.⁵ The civilian population

*Commissioner, Massachusetts Department of Public Health, and lecturer in public-health practice, Harvard School of Public Health.

Alan has, to a large degree, been able to control those infections for which he has been able to develop an artificial immunity by inoculation, such as smallpox and typhoid fever, and those diseases against which isolation is an important factor. Under wartime conditions, however, the control of infectious diseases is of military importance only

degree. Malaria has again taken its toll, but to a far greater principal European foci of these diseases. Similarly, in Poland, Russia and Romania, which are the decade preceding the war, have again increased relapsing fever, which had been decreasing during the incidents of typhus fever¹⁰ and of Scabies, impetigo and lice infestations are acute crowding in bomb shelters and concentration camps. insect-borne diseases have been intensified by the North Africa and Asia Minor.^{11, 12} The hazards of Europe and has extended into all of eastern Europe and has reached epidemic proportions throughout already played an important role.¹³ Typhus fever

In the present war, arthropod-borne diseases have thereby infect the indigenous arthropod vector.¹⁴⁻¹⁵ whom may bring infections back to their homes and infections, from carriers and from refugees, all of nized and treated cases but from those with latent of the United States does not arise from the recognition anticipated. With battles raging in all Large numbers of nonimmune susceptible persons are being concentrated in areas where insect-borne diseases are prevalent. With battles raging in all parts of the globe and principally in the tropics and subtropics,¹⁹ new hazards face the fighting men. Under battle conditions, they are being exposed to the added risk of the limitation of known effective control measures, unavoidable in the face of combat. To the classic list of military diseases, such as dysentery, typhoid, paratyphoid and typhus fevers and malaria,¹⁸ the military personnel have now the added risk of an entire galaxy of tropical diseases,¹⁷ many of which are insect borne. The problem presented by latent unrecognized infection¹⁶ and the carrier state among the military personnel cannot be fully appreciated. The similar problem presented by refugees in mass emigration from war-devastated areas or because of postwar treaties cannot be fully anticipated. The danger to the civilian population of the United States does not arise from the recognized and treated cases but from those with latent infections, from carriers and from refugees, all of whom may bring infections back to their homes and thereby infect the indigenous arthropod vector.¹⁴⁻¹⁵

in so far as these interfere with the task assigned to any military unit²⁰; and therefore, the main purpose of infectious disease control during wartime is guided by the principle of keeping as many men physically fit and in fighting trim as possible. In other words, the importance of a disease from a military point of view and the value of disease-control measures are determined in wartime by their effect or noneffect on the available fighting strength of a force.²¹ Insect-borne diseases are perhaps the most difficult and among the most important diseases with which military personnel are afflicted. For example,²² malaria was one of the main forces that defeated the American troops at Bataan²³; it again assumed major importance in the Solomons and on Guadalcanal.²⁴

A disease is classified as insect-borne²⁵ when a blood-sucking insect is the sole or the usual agent by which the infecting organisms are transmitted from one patient to another. This transmission may be from man through vector to man, from animal through vector to man, from animal through vector to animal and from man through vector to animal. The disease may have a wide host selectivity, and the vector may spread the disease from one genus of animals to another. On the other hand, many insects feed only on certain closely related species of the same animal, whereas other vectors are not so finicky about the type of blood they suck. Many insects prefer certain hosts and fly many miles to obtain this favorite blood, rather than bite some other species that may be near by. Occasionally, this zoophilic deviation of the insect vector can be used as a control measure in malaria.⁶ The importation of cattle may deviate the mosquitoes from man and thereby reduce the incidence of bites of man.

An insect-borne disease may be transmitted by only one genus or, in some instances, by only certain species or merely one species of insect. Other insect-borne diseases are spread by several different insects, entirely unrelated and of different genera. Dengue,²⁶ for example, was thought to be transmitted naturally by only two species of *Aedes* mosquitoes, *Aedes aegypti*²⁷ and *A. albopictus*,²⁸ but *A. scutellaris hebrideus* has been recently incriminated.²⁹ Malaria is transmitted by some twenty species of Anopheline mosquitoes.³⁰ Relapsing fevers are transmitted by both lice and ticks; and typhus fever by lice,³¹ fleas³² and mites.³³

CLASSIFICATION OF VECTORS

Many so-called "insect-borne" diseases are not transmitted by insects but by other genera.^{34, 35} The true insect is a hexapod and belongs to the class Insecta, such as the mosquito, fly, bedbug and louse. Other diseases are transmitted by the class Arachnida, which are eight-legged creatures, such as mites and ticks. The phylum including both the insects and the arachnids is Arthropoda — animals with jointed legs.

The class Insecta is composed of about twenty orders, of which five are incriminated directly or indirectly in the transmission of disease. These orders are Diptera (flies and mosquitoes), Anoplura (lice), Siphonaptera (fleas), Hemiptera (bugs) and Orthoptera (roaches). To these may be added sixth order, Hymenoptera (wasps, bees and ants) some of which bite or sting man and are a source of discomfort. Perhaps some future research may relate these insects to disease transmission.

The class Arachnida is composed of eleven orders of which only one, Acarina, comprised of ticks and mites, is known to transmit disease. The order Scorpionida (scorpions) and Araneida (spiders) cause discomfort by biting man but have not been incriminated as vectors of disease.

Arthropods may affect the health and well-being of man in several ways: by conveying disease, by invading the tissues of man, as in scabies, by inoculating poisonous substances,^{36, 37} such as in the bite of the black-widow spider, bee or wasp, and by being pests to man, such as bedbugs. This paper, however, is limited to a brief discussion of the diseases conveyed by arthropods and those of the arthropods themselves.

DIPTERA

Mosquitoes

The most important arthropods responsible for the transmission of disease are the true insects, in particular mosquitoes and flies. Mosquitoes transmit filariasis,³⁸ malaria,⁷ leishmaniasis,³⁹ tularemia,⁴⁰ yellow fever,⁴¹ dengue fever,²⁶ Rift Valley fever, equine encephalomyelitis,⁴² Japanese encephalitis⁴³ and St. Louis encephalitis.⁴⁴ Not all mosquitoes are vectors of disease; moreover, only the female is dangerous, as the proboscis of the male is not sufficiently rigid to penetrate the skin and hence it aesthetically lives on plant juices. Three mosquito genera are of special importance as vectors — Anopheles (malaria), Aedes (dengue fever, filariasis and yellow fever⁴¹) and Culex (filariasis, equine encephalomyelitis, Japanese encephalitis and St. Louis encephalitis).

Not all species of any genus are capable of transmitting disease, nor are all such species of equal significance as vectors. The important vector in any particular geographic area may be missing or unimportant in some other location. For example, in the United States by far the most important vector of malaria is *Anopheles quadrimaculatus*⁴⁵; in Italy, *A. maculipennis labranthiae*; and in Brazil, *A. gambiae*.⁴⁶ Although all mosquitoes develop by complete metamorphosis and the life cycle consists of eggs, larva, pupa and adult, all species do not breed under similar conditions.⁴⁷ Some species have only one brood a year, whereas others continue to breed throughout the year. Some lay their eggs in water-filled tree holes, and others prefer collections of water in tin cans and cisterns; still others breed in ponds, marshes, hoof-prints, puddles,

warm sunny ponds, cool running streams, or even brackish water.

The eggs of *Anopheles* are deposited singly in batches of forty to one hundred on the surface of the water and are provided with floats.⁴⁸ *Aedes* eggs are also laid singly in lots of twenty-five to fifty; they sink to the bottom, or when laid on the side of water receptacles, they may lie dormant for months, hatching only on favorable conditions of temperature and moisture.⁴⁹ *Culex* eggs are deposited on the water surface in rats of one hundred to four hundred.⁵⁰ In twelve to seventy-two hours the eggs hatch into larvae, which are actively mobile and feeding cylindrical organisms; they vary in color from gray, yellow or red brown to dark brown or black. Developing by repeated moulting, the larvae pass through four instars or forms, increasing each time in size. Under favorable conditions, the larval stage lasts about ten days. *Mosquito* larvae must breathe through a tube at the posterior end of the body. All mosquito larvae except those of *Anopheles* have a distinct siphon tube, by which they attach themselves to the surface of the water, the head being suspended downward. Since all species of *Anopheles* have only a tubeless opening, they lie parallel with the surface of the water, their heads being just under the surface. This position makes them more susceptible to poisoning from small particles that may float on the surface of the water. From the fourth instar, the larva develops into a comma-shaped pupa, which is a resting, floating stage during which a complete metamorphosis from larva to adult transpires. The nonfeeding pupae are supplied with two breathing trumpets on the dorsum; they are actively motile, being supplied with two paddle-shaped appendages. Locomotion is accomplished by rapid flexion and extension of the abdomen.

In about twenty-four to seventy-two hours the pupal case splits along the dorsum and the adult or imago gradually emerges, and as soon as the exoskeleton hardens the mosquito is ready for flight and food. Temperature and humidity affect the biting activities, mosquitoes usually being more active in hot humid weather. The flight range varies with different species; the flight of *Anopheles quadrimaculatus* is usually less than a mile, whereas *Aedes sollicitans*, a salt-water species, has been found fourteen miles from the nearest salt water.⁵¹ Moreover, mosquitoes, as well as other arthropods, may be transported by motor vehicles, ships and airplanes. Sailing vessels were responsible for transporting *Aedes aegypti* to Boston and other American ports from South America,⁵² thereby causing short-lived local outbreaks of yellow fever. The aeroplane was probably responsible for the importation of *Anopheles gambiae* to Brazil from Africa, thereby causing an extensive and severe outbreak of malaria.⁵³ The adult female mosquito, under favorable conditions, usually lives as long as three months. Fortunately, however, many succumb to the vicissitudes of their environment — natural enemies, adverse weather and other unfavorable conditions. Hence, the normal life expectancy of a female adult mosquito is probably two to four weeks.⁵⁴ Certain species of mosquitoes, however, hibernate throughout winter as adults. Thus, *Culex* and *Anopheles*, in temperate zones, survive as gravid females and some species of *Anopheles* hibernate as larvae. *Aedes* usually survives from one breeding period to another as eggs. In colder regions nearly all species survive winter as eggs, but in the tropics and subtropics unfavorable periods may be survived by retarded or slowed development.

The biting, breeding and flight habits of mosquitoes vary from place to place and from one species to another. It is therefore absolutely necessary to conduct a mosquito survey or to have available detailed information relative to the particular insect-borne disease, its vectors and the ecological factors that are likely to bear an important role in the determination of effective and efficiently employed control measures.⁵⁵ These factors may also influence the location of camps or semipermanent institutions, such as airfields and hospitals, in relation to other population groups or settlements in the general vicinity. Similarly, the success of a military campaign may be adversely affected by lack of true evaluation of the vectors and their habits. The identification of mosquitoes is a difficult but necessary task.⁵⁶ It is usually accomplished by a key prepared for certain geographic sectors.^{55, 56} Such identification into species is performed with a dissection microscope and may usually be done on both larvae and adults. *Mosquito*-control measures must be guided by preliminary identification surveys,⁵⁷ as well as by periodic catches of both larvae and adults to evaluate the effectiveness of applied measures. Control measures must be selective and applied only to those species that are vectors of the disease for which control is being exercised, since money, time and labor might otherwise be expended lavishly for controlling harmless mosquitoes. Similarly, nuisance mosquitoes must be controlled if effective results are to be expected. *Mosquito*-control measures are usually classified as temporary or permanent.⁵⁸ Temporary measures are the application of larvicides,⁵⁹ spraying with insecticides⁶⁰ and the use of insect repellents.⁶¹ Permanent control measures include flooding,⁶² drainage and the construction of ditches, dams or special siphon apparatus⁶³ for the automatic changing of water levels. The choice of method⁶⁴ depends on the availability of time, labor and funds and the desired result.

Flies

Whereas all true mosquitoes belong to the family Culicidae, suborder Nematocera of the order Diptera, flies are members of three suborders.⁶⁵ The suborder Nematocera includes moth flies, midges and gnats, all of which contain members that are

disease vectors and are blood-sucking insects. The suborder Brachycera includes the large-bodied horseflies and deer flies. One genus, *Chrysops*, blood-sucking flies, includes the vector of tularemia and of loasis, a filarial disease. The remainder are important to man only as pests, many not being blood suckers. The suborder Athericera includes the common housefly and related "filth" flies. They are important in the mechanical transmission of disease, especially under primitive environmental sanitation and on the battlefield; many of their larvae are myiasis producing. Some are vicious biters and pests of man. One genus, *Glossina*, contains the vector of African sleeping sickness.

Identification of flies depends on classification into suborders on their antennal characteristics and thereafter on the structure of their mouth parts, wings and body. Any dipterous insect possessing mouth parts capable of piercing the skin of man must be regarded as a potential vector of blood-inhabiting, pathogenic micro-organisms; insects with nonpiercing mouth parts obviously cannot be responsible for introducing infection directly into the circulation except through previously injured surfaces. Thus, by inspection of the mouth parts, the insect's disease-conveying hazard may be estimated.

Nematocera. Of the suborder Nematocera, family Psychodidae, only one genus, *Phlebotomus*, is blood sucking and responsible for transmitting disease.⁶⁶ Pappataci fever (sandfly fever),^{67, 68} bartonellosis (oroya fever)⁶⁹ and leishmaniasis (kala azar and oriental sore⁷⁰) are transmitted by *Phlebotomus*. In addition to being vectors the sandflies are vicious biters.⁷¹ *Phlebotomus* flies are minute in size and have extremely hairy bodies and wings. As in mosquitoes, only the female is capable of biting and spreading disease. Eggs of these flies are deposited in batches of fifty in dark, moist crevices in walls, caves and embankments. The larvae feed on organic and excremental debris. After four months a naked pupa is formed, from which the adult emerges; the life cycle is six to eight weeks from egg to adult.

The adults of the nonbiting species of Psychodidae are frequently found in kitchens and out-houses, along creeks filled with decaying matter and about sewage-disposal plants. The larvae are found in decaying vegetable matter, sewage, manure, exuding sap of trees and foul streams.

The *Phlebotomus* sandflies lay their eggs in crevices of rocks and in damp cracks in shady soil or floors.⁷² The adult sandfly varies from 1 to 3 mm. in length and hence can crawl through the meshes of an ordinary mosquito net. Its bite is extremely annoying and may cause a great deal of irritation. The females feed exclusively on blood; they often feed once and die after oviposition, but most species feed at least twice or oftener. They are nocturnal and seldom bite except at night; in some places they

seem to forage for only an hour or two after sunset. During the day they hide in darkened corners, cellars and crevices and under floors and rocks. Their flight is limited, and when disturbed on walls, they usually fly only a few inches. Their breeding places are nearly always within a few hundred feet of where they feed. Dimethyl phthalate has been used as a repellent in control of *Phlebotomus*.⁷¹

The same suborder contains the family Simuliidae, which has only one disease-transmitting genus, *Simulium*, the buffalo gnats and black flies. Species of *Simulium* act as vectors of larvae of *Onchocerca volvulus*, the filaria responsible for onchocerciasis.⁷³ Female buffalo gnats are also vicious and persistent biters. The eggs, in masses of five hundred, are small, glistening and yellow; they are laid on stones and vegetation in swiftly running streams. The larvae, by a posterior sucker, attach themselves to rocks and maintain their position in the current. The brown or green larvae move from one spot to another and tend to congregate in dense, slimy, mosslike groups on stones and other substrates. The full-grown larvae become enclosed in cone-shaped cocoons below the surface of the water. The entire life cycle requires ten to thirteen weeks, but *Simulium* may hibernate through the winter either in the egg or in the larval stage. Since black flies breed in running water, the methods to be employed in their extermination are quite different from those ordinarily used. The reducing of river flow by damming at intervals, leaving falls between, or, in the case of small brooks, the construction of underground channels are effective measures. In some instances, sweeping stones and other substrates with brooms is of value. Furthermore, the clearing of debris from a stream deprives the larvae of a fastening place. Repellents that are effective against mosquitoes also afford protection against black flies. These flies rarely enter houses, hence fumigation is usually unnecessary. Smudges are beneficial for the protection of both men and animals. The black fly bites freely during daylight.

A third family, Ceratopogonidae, of the same suborder, Nematocera, contains sandflies, no-see-ums, biting midges and punkies. This family includes three genera, of which one, *Culicoides*,⁷⁴ is the vector of filaria. Although species of *Acanthocheilonema* and *Mansonella* are considered nonpathogenic to man, they are extremely annoying to both man and animals wherever they are abundant. These flies are extremely small and have light and dark ornamental markings on the wings. Only the female bites. Eggs are usually laid in water or water-saturated sand or soil. The white threadlike larvae develop into slender brown pupae, which may be mistaken for mosquito pupa because of two short breathing tubes on the thorax. The life cycle requires six to twelve months; *Culicoides* go through the winter either in the egg or in the larval stage.

The great majority of the species that attack man

They are mechanical transmitters of disease and household pests to man.

The genus *Glossina*, which includes all species of tsetse flies,⁷⁵ is chiefly limited to tropical Africa; these flies are the vectors of Gambian and Rhodesian sleeping sickness. Both the male and female are blood sucking. The female is viviparous and carries a single larva at a time. This larva is deposited, fully developed, in dry sandy soil in shady places. The larva burrows down about 5 cm. and pupates. One species occurs in the southwestern corner of Arabia. Tsetse flies⁷⁶ are by no means evenly distributed over these great areas, being limited locally to the so-called "fly-belts," chiefly along rivers and at the edges of lakes. They are migratory, especially from minor water collections that may be drying up to larger and more permanent bodies of water. They are diurnal in habits. *Glossina palpalis* is most active in the middle of bright days, and *G. tachinoides* on dull days and in the morning. *G. morsitans* is active in the morning and afternoon but disappears at midday; *G. brevipalpis* and *G. longipennis* bite from sunrise until about 8:00 a.m. and from about 4:00 p.m. until dark. Tsetse flies are attracted by color, especially black and brown, and are repelled by white. When accompanied by flies. Black or dark clothes are preferred to light-colored ones, and khaki appears particularly attractive to them. Insect repellents, flyproof clothing or veils and the wearing of white clothing are effective control measures. Passing through the fly-belts at night is the best method of avoiding tsetse flies. Clearing away brush along streams infested with *G. palpalis* and *G. tachinoides* is effective in preventing breeding. Tsetse flies seldom go more than fifty yards from the brushy borders of streams except when following prey, when they may fly several hundred yards. Therefore, if brush is cleared away for thirty yards from the edges of water in the vicinity of fords, villages, washing places and so forth, the flies quickly disappear.

Stomoxys, the stable fly, has been frequently used in the experimental transmission of disease. Although naturally infected specimens have not been found, it is best to consider it as a potential vector of tularemia and other diseases. It is about the size of the common housefly, often enters houses, especially before rains, and is responsible for the belief that the housefly bites. *Stomoxys calcitrans* may be noted resting in sunny places on the walls of stables and farm buildings.⁸⁰ It breeds primarily in excrement and often can be recovered in abundance in scattered material at the edges of old hay- and strawstacks and in the organic debris often washed up along the seashore. The flies are cosmopolitan in distribution, and control measures are principally local procedures to eliminate breeding in such material.

and animals belong to the genus *Culicoides*, which lays its eggs on or near water, the larvae living in water or in water-saturated mud or sand. Many favor brackish or salt water. A few species belong to other genera, *Leptocnops* and *Forcipomyia*, which breed for the most part in damp places under bark, stones and moss. Nearly all the blood-sucking species become active at dusk; if disturbed, they also bite on bright days in the shade. They are active fliers, often going over half a mile in search of food, but only when the air is still. The bites of *Culicoides* produce nettle-like pricks, which may be followed by burning sensations and intolerable itching. Control by larvicides is impractical; smoke smudges and oily repellents seem to be more effective. Because of their small size they can penetrate ordinary screen and nets.

Brachycera. The suborder *Brachycera* contains only one family, *Tabanidae*, with only one genus, *Chrysops*, that transmits human disease. Horse-flies, deer flies and mango flies are common names for flies of this suborder. Females of the species of the genus *Chrysops* are vectors of tularemia⁸¹ and loasis.⁸² Two other genera, *Tabanus* and *Hematomys*, are important only as pests. Some species act as pests to animals and transmit certain animal diseases, such as anthrax, surra, el dehab and swamp fever; they have also been incriminated in Russia as vectors of tularemia.⁸³ Eggs, in gelatinous masses, are laid on leaves of aquatic plants overhanging sloughs and swamps. In about a week, the larvae hatch and drop into the water or moist ground. They are elongated, tapering sharply at both ends, and have marked ridges at each segment. In several months the fully developed larvae work their way into drier ground, pupate and in two or three weeks emerge as adults. The life cycle requires three to twelve months; overwintering occurs in the egg or larval stage. Because of their peculiar breeding habits, horse-flies, deer flies, mango flies, green-headed flies and other *Tabanidae* are difficult, if not altogether impossible, to control in the immature stages. Oil films on water may be effective in killing larvae as they hatch from eggs and drop into the underlying water.

Athericera. This suborder, family *Alusidae*, contains one genus, *Glossina*, that is a vector of a human disease, African sleeping sickness. Other genera of *Alusidae* are important as mechanical carriers of typhoid and paratyphoid fevers, cholera and bacillary and amebic dysentery. In a large number of genera, the larvae may be tissue parasites of man, producing myiasis. The blood-sucking group of these flies include the genera *Glossina*,⁸⁴ *Stomoxys* and *Hæmatobia*; they are vicious biters and vectors of disease. The nonblood-sucking flies include the genera *Alusca*, *Fannia*, *Hippelates*, *Sarcophaga*, *Calliphora*, *Chrysomya* and *Lucilia*.

Species of *Haematobia*, horn flies, are a serious pest of cattle but rarely attack man. They are blood-suckers and closely resemble the housefly.

Musca domestica, the common housefly, develops in animal and vegetable refuse that accumulates about farms and houses.⁸¹ It is almost ubiquitous since its preferred larval foods are manure and fecal wastes, which are usually available near human habitation. It is responsible for the mechanical transfer of enteric disease-producing micro-organisms from fecal material to food.⁸²⁻⁸⁴ It is often mistaken for the stable fly, *Stomoxys calcitrans*, and the latrine fly, *Fannia scalaris*. The latter is frequently seen hovering in mid-air in the middle of the room.

The housefly develops by complete metamorphosis, through the egg, larval, pupal and adult stages each of which requires certain definite environmental conditions.⁸⁵ The white, glistening oval eggs are about 1 mm. in length and are deposited in masses of one hundred to one hundred and fifty on or in moist organic matter. The female lays two to four batches in her lifetime. At 85 to 90°F., the eggs hatch in eight hours; at temperatures of 60 to 68°F., in twenty-four hours; and below 40°F., in two or three days. The cylindrical, gray or creamy-white, segmented, wormlike larvae or maggots are highly mobile and burrow into the fermenting mass, reaching maturity in four or five days under favorable conditions. The larvae leave the moist warm environment and migrate to pupate in a dryer and cooler place. The immobile, brown pupal stage lasts three to ten days, whereupon the adult fly emerges, crawls upward through the soil or manure and, as soon as the wings harden, is ready to fly. The female reaches sexual maturity and oviposition begins in from two and a half to twenty days. Under proper environmental conditions the egg-to-adult metamorphosis may be as short as seven days. The optimal temperature for flies is about 90°F.; they are quickly killed in wet material at 108°F. or by a temperature of 115°F. in a dry environment. The housefly does not bite. It cannot ingest particles larger than 0.045 mm. in diameter. Larger substances, such as grains of sugar, are first dissolved by regurgitation of liquid. The housefly is attracted to food principally by odor; it is a persistent and greedy feeder, storing food in its crop, an esophageal diverticulum. The normal flight range of the housefly does not exceed one thousand yards; however, if food is lacking they may migrate as far as a mile, principally in the direction of the prevailing winds. The usual life span is about one month. In the fall many flies are killed by a parasitic fungus disease, *Empusa muscae*. Houseflies are rendered inactive by low temperatures and are killed at 10 to 15°F. They hibernate over winter in the larval or pupal stage.

Green-bottle flies belong to the genera *Lucilia* and *Chrysomya*. They are scavenger flies, de-

positing their eggs on fish and decaying meat, on human and animal excrement and in open wounds. The thorax and abdomen of *Lucilia* are metallic green or bluish green and lustrous. The life cycle is similar to that of the housefly. The gray "flesh" flies, *Sarcophaga*, have a large body. The female is larviparous. The bluebottle flies, *Calliphora*, are scavengers, feeding on fish, decaying meat and human or animal excrement. They are of robust size and have a blue or metallic sheen to their bodies. All these flies may act as mechanical vectors of enteric infections.

The eye gnats, *Hippelates*, are vectors of yaws and of infectious conjunctivitis.⁸⁶ They are small in size and persistently return to feed on lachrymal secretions even though repeatedly brushed away. They do not bite but have spines on their mouth parts that cause lesions of the skin, through which infection may take place.

Certain species of flies can produce myiasis, a condition wherein fly maggots or larvae live parasitically in the organs and tissues of man and animals. Clinically, myiasis may be classified according to the part of the body invaded.⁸⁷ The larvae of *Chrysomya bezziana* are the usual cause of human myiasis in India. Other examples are species of *Dermatobia*,⁸⁸ tropical warble flies, and of *Hypoderma*, cattle botflies. Other flies that normally live in decomposing matter but which occasionally lay eggs in living tissues, being attracted by foul discharges and blood, are *Chrysomya macellaria*,⁸⁹ the American screw worm, and species of *Lucilia*, green-bottle flies and of *Sarcophaga*, gray flesh flies.

The eggs or larvae of some flies may be swallowed, usually in food or drink. The larvae often develop in the intestine,⁹⁰ but this occurrence is accidental and not a part of the normal development. Examples of this type of myiasis-producing flies are included in the genera *Calliphora*, *Sarcophaga*, *Musca*, *Fannia*, *Eristalis* and *Stomoxys*.

CASE 31111

PRÉSENTATION OF CASE

A forty-three-year-old factory proprietor was admitted to the hospital because of increasing dyspnea and dependent edema.

The patient was well until three years prior to admission, when he developed shortness of breath on exertion, edema of the ankles and legs, and weakness. He was admitted to a community hospital, where he was treated for heart failure over a period of four weeks, following which he returned to work believing himself to be entirely well. He continued to work and, except for an increasingly bloated feeling, was essentially free from symptoms until about one year prior to entry, when he again developed dyspnea and edema, progressing to a point that made hospitalization necessary. He remained in the hospital for twelve weeks and was discharged improved, but some dyspnea and edema were still present. He was unable to return to work, remaining at home resting and receiving diuretic injections once or twice a week. In spite of these measures, he noted a gradually increasing bloated feeling and abdominal distention. He was admitted to the hospital for study.

The patient recalled no childhood illness or definite rheumatic infection. He had had an attack of gonorrhea thirteen years previously and had recovered promptly after treatment. He had lost about 20 pounds in one and a half years.

Physical examination revealed a rather thin man in no acute distress who became somewhat short of breath on slight exertion. The skin appeared moderately atrophic over the whole body, and there was little subcutaneous tissue. Pitting edema was present, most marked over the sacrum, extending up the back, and to some extent in the lower extremities. There was questionable early clubbing of the fingers. The pupils reacted slowly to light and accommodation. There was some stiffness and limitation of motion of the neck in all directions, with poor muscles and a large, dilated, pulsating vein on the right. There was moderate scoliosis, with the thoracic concavity to the right, and slight lordosis. The thoracic cage showed little motion and flared out asymmetrically. There was dullness

*On leave of absence.

at both bases, more marked on the left, with decreased fremitus and diminished breath sounds. No rales were heard. The heart appeared enlarged. The left border of dullness was about 9.5 cm. from the midsternal line and 1 cm. outside the mid-clavicular line. There was questionable enlargement to the right. The point of maximum impulse could not be felt. The rhythm was irregular, with an extra beat and an occasional coupling for short periods. The sounds were of fair quality. A Grade 2 to 3 systolic murmur was audible over the lower end of the sternum and apex. No diastolic murmurs were heard. The liver extended to the level of the umbilicus. It was firm and nontender, with a smooth surface and a smooth sharp edge. The spleen was easily palpable, firm and nontender. The radial arteries were thickened but not tortuous, and no pulsations could be felt in the pedal vessels. There was some limitation of motion in all joints, especially the elbows, but there was no pain or crepitus on manipulation.

The temperature was 98.6°F., the pulse 50, and the respirations 16. The blood pressure was 110 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 4,610,000, with 13.6 gm. of hemoglobin, and a white-cell count of 10,200, with 78 per cent neutrophils, 8 per cent lymphocytes, 10 per cent monocytes, 2 per cent eosinophils and 2 per cent basophils. The red cells and platelets were normal. The urine had a specific gravity of 1.016, with a + test for albumin and a few white cells in the sediment. The serum protein was 4.4 gm. per 100 cc. A blood culture was negative. A blood Hinton reaction was negative. A bromsulfalein test showed 15 per cent dye retention in the serum. An antecubital-vein-to-mouth circulation time with Decholin was 36 seconds. The venous pressure ranged between 12 and 15 cm., the veins filling and emptying with the heart cycle.

A roentgenogram of the chest revealed considerable fluid in the left pleural cavity obscuring the diaphragm and producing some compression of the lower lobe. A small amount of fluid was also present in the right costophrenic sinus. The visible lung fields were clear except for a healed Ghon's complex on the right, with calcification in both hili. The heart showed a marked general enlargement, with a transverse diameter of 17 cm., as compared to an internal chest diameter of 27.5 cm. Pulsations of the heart were slow, but the amplitude was within normal limits. There was no dilatation of the left auricle. Examination of the esophagus showed no delay in the passage of barium and no evidence of varices.

An electrocardiogram on admission (Fig. 1) revealed an almost regular ventricular rhythm, with a rate of 60, and frequent ventricular premature beats from varying foci. There was no discernible auricular activity. There was an extremely low

at the time of onset was forty-three years old — not twenty-three, or sixty-three, but forty-three. In the second place, he had been having symptoms for something in the neighborhood of three years; for over a year these had been more or less fixed but present most of the time. It seemed to me as I read the story that over a three-year period he had had rather less fluctuation in the course of his disability than many people with progressive types of cardiac disease. I began to think about the kinds of cardiac disease, if this should turn out to be cardiac disease, which can give a slowly progressive, fixed type of voltage of the QRS complexes, and almost flat T waves in the standard leads, with slight sagging of ST₁ and ST₂. Lead \pm showed an absent R₁, a slightly elevated ST and a flat T.

The patient was placed on a cardiac regimen, including a low-salt diet, limitation of fluids, 0.1 gm. of digitalis daily, ammonium chloride and Mercupurin. An electrocardiogram on the seventh hospital day showed no change except for disappearance of the ventricular premature beats and a somewhat slower rate. Precordial leads revealed a tendency to low voltage, with absent R waves in Leads 1, 2,

FIGURE 1. *Electrocardiogram on admission.*

3 and 4. The T waves were low and upright in Leads 1 and 2, diphasic in Lead 3 and inverted in Leads 4, 5 and 6.

The patient continued unchanged except for a brief upper respiratory infection on the tenth and eleventh hospital days, during which the temperature rose to 102°F. but rapidly returned to normal. The pulse continued slow. A left thoracentesis on the twenty-third hospital day was productive of 150 to 200 cc of clear straw-colored fluid, which was negative on culture.

On the twenty-fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

Dr. C. SIDNEY BURWELL*: I should like to draw the picture of the way this disease began. In the first place, it seems to me significant that the patient

*Research professor of clinical medicine, Harvard Medical School

had no evidence of acute congestion of the lungs, other variety of obstruction? It is striking that he

If he did not have tricuspid stenosis, had he some patible with that as a primary situation.

degree of venous distention that is usually compatible with that as a primary situation. suggestion in his x-ray films, nor did he have the usual. He had no signs of it in his murmurs, and no stenosis without its older brother is extremely unusual. He did not have mitral stenosis, and to have tricuspid he did not have tricuspid stenosis. In the first place, There are many reasons to believe that this man from variations in the capacity of the myocardium. tions that are frequent in people who are suffering the liver, often with edema but without the fluctuation of peripheral congestion, with enlargement of With tricuspid stenosis there is apt to be a long history. One immediately thinks of tricuspid stenosis.

do that. disability. There are several conditions that will

that he had primarily peripheral congestion and that the dyspnea was never paroxysmal and was not present at rest but occurred when he tried to exert himself. This suggests that the dyspnea was due to inability on his part to increase cardiac output or the respiratory volume.

Another type of obstruction to circulation that he might have had is pericardial disease. If he had pericardial disease with this history it would certainly have been chronic pericardial disease, and it might have been that interesting disorder called "constrictive pericarditis," which Dr. White^{1,2} began to study actively in 1928. I shall come back to that presently.

A third possibility is pulmonary heart disease with cor pulmonale. This would account for slow progression without much fluctuation. Cor pulmonale is an interesting disorder, which may be based on a good many kinds of changes in the pulmonary circulation and which is usually marked by right ventricular failure. Perhaps he had right ventricular failure, but he had no cyanosis, no evidence of extensive lung disease, no history of cough anywhere in this record. If he had cor pulmonale he must have had an unusual form of primary pulmonary hypertension, and I do not find any evidence of it. There are other disorders that lead to right-sided failure, and the most frequent is mitral stenosis. He might have had mitral stenosis, with right ventricular failure of a rather fixed type, but the evidence in the murmurs, in the history and in the x-ray films is against it.

Could this form of symptoms result from a myocardial infarct on the basis of vascular disease? Occasionally, although rarely, one sees vascular degeneration of the myocardium almost limited to the right ventricle. In such a situation this history might be possible.

I want to consider in a moment the possibility that this was not cardiac disease at all, at least not primarily, because there are certain interesting suggestions that other organs were involved in an important way. Before doing that, I should like to review and perhaps get a little help on one or two bits of evidence that are presented. In the first place, the venous pressure is recorded as equivalent to 12 to 15 cm. of water. It is particularly necessary in a man with an abnormal chest to know how that was measured. How was the zero point determined?

DR. EDWIN O. WHEELER: It was determined by measuring 5 cm. down from the sternum rather than 10 cm. up from the back.

DR. BURWELL: I should also like to know what the anteroposterior diameter of this man's chest was.

DR. WHEELER: I do not know.

DR. BURWELL: Could you guess? Was it increased or normal?

DR. PAUL D. WHITE: I should say that it was normal.

DR. BURWELL: That is comforting. On this x-ray film it looks increased. Would you agree, Dr. Holmes?

DR. GEORGE W. HOLMES: Yes.

DR. BURWELL: These measurements are important. Assuming that this is a cross section of the chest and the heart is lying here, if you measure 5 cm. down from the sternum, you hit the level of the right auricle. If you measure 10 cm. up from the back, you hit about the same level. If a man has an emphysematous chest, that relation of the heart to the back does not change, but the anterior chest wall in effect is lifted off the heart. Thus, if you measure 5 cm. back from the sternum, you get your level above the right auricle and therefore get a false low venous pressure. Every now and then one sees obvious right ventricular failure and a normal venous pressure, and in a fair percentage of these patients the normality of the venous pressure is the result of error in the placing of the zero point. When you put it somewhere near the position of the right auricle you find that the pressure has a high pressure. I take it that this man had venous distention and a venous pressure that was above the usual level of normality by the Moritz and von Tabora³ method, but not much. I am inclined to regard 12 to 15 cm. as a high venous pressure in this man. He had a thick chest, so that one should probably add 5 to 6 cm. to the measurement.

DR. WHITE: What would you put as the top normal measurement according to your method?

DR. BURWELL: Using a zero point 10 cm. above the back, all our measurements in normal persons were under 15 cm., and 90 per cent of them were under 13 cm.

DR. WHITE: These readings are doubtless higher than those one would obtain with the subject in the vertical position. Twelve to fifteen centimeters is actually greater than the distance from the level of the clavicle to where the superior vena cava enters the right auricle; so I think that your readings may be too high from the standpoint of the actual or true venous pressures.

DR. BURWELL: Yes, but the arm-vein pressure is sensibly higher than the auricular pressure. If one takes 100 normal people and measures the venous pressures with the Moritz and von Tabora method, with the zero point 5 cm. down from the sternum, and charts them against the anteroposterior diameters of the chest, one gets, in general, a good correlation. The bigger the chest, the lower the venous pressure. If one charts the venous pressures determined by using the zero point 10 cm. from the back against the diameters of the chest, there is no correlation. It is an important point.

I am satisfied that this man had a high venous pressure. That is what I wanted to be sure of.

DR. WHITE: The neck veins were engorged.

DR. BURWELL: It is true that there is a statement about distended, pulsating neck veins that col-

no widening in that area, but this film was taken to bring out the right border.

The shadow in the lower part of the left chest is obviously fluid. In the films taken sixteen days later, one can see that the fluid has largely disappeared, although not completely.

DR. BURWELL: Do you see any evidence of calcification in the region of the heart?

DR. HOLMES: No. As you pointed out, I do not believe that the patient had enough scoliosis or emphysema to account for any of these things. I suppose that these calcified lymph nodes around the root of the lung are of some interest if one is thinking of tuberculous pericarditis. There is evidence that he had had a tuberculous infection at some time.

DR. BURWELL: The lungs are singularly clear.

DR. HOLMES: Yes, with the exception of this fluid. The interlobar fissure is visible, but I do not believe that it means anything. It may mean that the films were taken at exactly the right tilt.

DR. BURWELL: That is helpful to me.

DR. WHITE, with his characteristic precision, has recently studied the size of the heart in constrictive pericarditis. Many workers were entranced with the thought that here was a situation where one could observe severe evidence of cardiac failure with a normal-sized heart, and placed considerable emphasis on this point. But being a systematic kind of fellow, Dr. White set out to see how many of his patients with constrictive pericarditis had an enlarged heart, and it came out that 40 per cent had appreciable enlargement. Therefore, the fact that this heart was enlarged does not rule out constrictive pericarditis. But enlargement of this degree is unusual in constrictive pericarditis, not many of anybody's cases having had this much. Therefore one again gets a warning signal.

In favor of constrictive pericarditis is the fact that there is no other obvious explanation for this man's heart failure, except one to which I shall refer in a moment. He had no evidence of valvular disease, no evidence or history of hypertension and no evidence of congenital heart disease that I can find, and in so far as the evidence of these things is missing he falls into the type of persons who might have constriction. He had one other suggestive thing, namely, thick radial arteries. He had no pulsations in his feet and he had a complex electrocardiogram, and the question arises whether this man has to be classified on the basis of vascular degeneration of the myocardium. I allowed the pleasant thought of coarctation to pass through my mind when I read about the feet, but he had no hypertension or other things that go with coarctation and I see no great notches in his ribs, no collaterals and so forth, so that we can lay coarctation aside.

Could he have had some rare kind of occlusive arterial disease that shut off the arteries of the feet?

aped and filled with the action of the heart, but it does not say what position the man was in when that was observed and I wanted a little reassurance. I think the question of venous pressure is an all-important one.

There is an interesting variety of cardiac disorder, associated with severe kyphoscoliosis, that is called "pulmonocardiac failure." This was admirably described by Chapman, Dill and Graybill a few years ago. The disability is largely one of ventilation, and the involvement of the heart in the composition of that picture is relatively small. Here is a man with slight scoliosis, and he may have had some limitation of excursion because of the relative immobility of the chest, but I do not believe that he had heart failure on the basis of the chest deformity, nor do I believe that all the symptoms can be explained on the basis of emphysema, some fixation of the ribs and loss of elasticity of the lungs, although all of these were probably present.

In considering some of the matters that have been tossed up with regard to the varieties of heart disease leading to obstruction or right ventricular failure, two important observations are that the heart was considerably enlarged and that the enlargement was not associated with a great reduction in excursion. An interesting question immediately comes to mind. In the x-ray and fluoroscopic examinations the amplitude of pulsation is said to have been within normal limits. The amplitude of the heart excursion is most closely related to the amount of blood that it expels per beat, and the amount of blood expelled with each beat has an important relation to the rate of the heart. He maintained a cardiac output of 4 liters per minute. The heart does not have to expel as much per beat if beating at a rate of 100 as it would if it were beating at a rate of 50, and the excursion would be smaller at a rate of 100. I should like to know if this excursion was normal for a rate of 50 or normal for a rate of 80.

DR. HOLMES: You have raised an interesting point, and one that I cannot answer. I do not believe that radiologists, at least those in this hospital, pay as much attention to that as they might. When the radiologist observes the heart with the possibility of an adherent pericardium in mind, he notes whether or not the amplitude of the beat is diminished, regardless of the pulse rate.

This heart is somewhat triangular in shape, which is slightly in favor of an adherent pericardium.

DR. BURWELL: The landmarks are not striking. It is rather an expressionless kind of heart silhouette.

DR. HOLMES: There is another point, if one can be certain about it; namely, one cannot distinguish the auricle from the ventricle along the left border. This is a difficult observation, particularly in a patient with fluid in the chest. It is not well seen. With an adherent pericardium or pericarditis with effusion, there is usually widening of the mediastinal shadow above the heart. This man certainly has

without giving symptoms of interference with the arteries in the myocardium and without causing local symptoms? I think that is unlikely.

I want to talk briefly about the confusing electrocardiograms. There are certain things that are entirely compatible with chronic pericardial disease. The characteristic things in constrictive pericarditis are low voltage and flat T waves. He had both of these, but he had some other things that are suggestive of anterior infarction. There was a slightly elevated ST, and an absent R in the precordial leads, with a variation in T waves in the precordial leads, which is also compatible with anterior infarction. The T waves in the limb leads are not like those of anterior infarction, and the low voltage is much more like pericardial disease than coronary disease in its unanimity in all the leads. I am not at all sure that a good thick layer of something over the myocardium would not interfere with the electrical activity in much the same way that an area of dead muscle in the same position would. I do not see any theoretical reason why a pericardial scar would not imitate an anterior infarction from that point of view. Also, as you well know, one of the characteristics about tuberculous pericarditis is that it is always accompanied by subpericardial myocarditis of varying degree and extent, and this may also lead to abnormal electrocardiographic manifestations. I am therefore inclined to find a good many difficulties in pinning a diagnosis of active coronary disease or of significant coronary occlusion on this man. There was no pain to suggest it, and not the fluctuation in the course that is usually produced by successive occlusions, and I think that the electrocardiogram can perhaps be explained on another basis.

I should like to introduce a discordant note and suggest that perhaps the whole picture was caused by cirrhosis of the liver. He had a number of things that go with cirrhosis of the liver. He had a big liver, a low protein and atrophic skin. On the other hand, he had no ascites, no varices and no spider telangiectases. He had had this thing too long, I believe, without ascites for it to have been cirrhosis of important degree. Moreover, although he had an enlarged spleen, I think that this and the increase in connective tissue in the liver were probably secondary to cardiac congestion and not to a primary cirrhotic process. The hypoproteinemia is rather important in the business of producing his symptoms, because when one has a total protein of 4.4 gm. the chances are that the albumin is severely reduced. The osmotic pressure is correspondingly reduced, and the transference of fluid to tissues is greatly facilitated. Under these circumstances a relative, slight increase in venous pressure may be important in causing edema, and I suspect that, so far as the edema goes, this man's low protein was quite as contributory as the dynamic situation created by his increased venous pressure.

I shall therefore make a diagnosis of constrictive pericarditis in this man, in spite of several points against it and in spite of the fact that not one of the usual cardinal signs was present. He had no evidence of calcium in the pericardium, he had no pulsus paradoxus, he had no ascites, although he had had congestion for three years, and his heart was certainly on the big side. I think more of the findings can be explained by constrictive pericarditis than by anything else. My second choice is localized arterial disease of the right ventricle, with myocardial degeneration, but I think that is a poor second, and I shall rest the case on constrictive pericarditis. If it was that, it was probably due to tuberculosis.

DR. WHITE: Dr. Burwell saw this patient during life but doubtless does not remember him. The note that he wrote at that time is certainly consistent with what he has just said. In December, 1943, he wrote:

This man has had fixed congestion for about one and a half years, preceded by intermittent congestion for a year. He exhibits distended veins, a feeble apex beat and a small pulse pressure (105/80) in spite of a rate of 48. He has no evidence of valvular disease. He has a large liver and edema. The lung descends in front of the heart. The chest moves in a limited way (vital capacity, 1500 cc.), and there is fluid and probably fibrous pleuritis at the left base. I believe that he has a constrictive pericarditis and that operation is justified. It is possible for extensive myocardial disease to produce the same picture, but I see no evidence of it. Two problems must be considered in the postoperative course—the low protein in the blood and the limited vital capacity. Removal of the pleural fluid would help the latter. Fluoroscopically the impressive things are a moderate increase in heart size and a marked limitation in the movement (excursion) of the heart in spite of the slow rate.

We both examined the patient fluoroscopically, if you recall.

DR. BURWELL: I begin to remember him, but I do not recall what fluoroscopy showed.

DR. WHITE: It seemed to us that he had a large heart that was somewhat limited in excursion. I asked you to come down because I wanted moral support for surgical exploration on account of the possibility of constrictive pericarditis. As a matter of fact, I do not remember exactly what I said myself at that time. Is there a note by me?

DR. WHEELER: We agreed essentially with Dr. Burwell that the case was not characteristic of constrictive pericarditis but that no other good diagnosis could be made. We thought that the man deserved a chance of help by operation.

CLINICAL DIAGNOSIS

Constrictive pericarditis (? type).
Heart disease of other nature?

DR. BURWELL'S DIAGNOSIS

Constrictive pericarditis.

ANATOMICAL DIAGNOSIS

No evidence of constrictive pericarditis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: An exploratory thoracotomy, performed by Dr. Sweet on the twenty-fourth hospital day, revealed 100 cc. of clear, straw-colored fluid in the pericardial sac. The sac was not thickened, and no adhesions were present. The pericardial fluid proved to be negative for tubercle bacilli on guinea-pig inoculation. Following the operation the patient continued as before, with periods of congestion relieved periodically by diuretics, and he was discharged on the forty-first hospital day.

We shall now continue with this patient's second admission, Dr. Burwell, and give you another chance.

DR. BURWELL: That is wonderful. Opportunity is supposed to knock but once.

ADDITIONAL HISTORY

Following *second admission* (six months later). The patient seemed somewhat improved and remained up and around on a regimen of limited fluids, digitalis, ammonium chloride and periodic courses of mercurial diuretics. He complained of occasional mild pains and aches in the right shoulder, elbow and fingers, apparently unassociated with fever. He also noted an aching pain, occasionally sharp, over the region of the precordial incision, without radiation or relation to exertion; it did not respond well to morphine. About six weeks prior to admission he became rather suddenly worse, with increased congestion in spite of diuretics; he was confined to bed, and several chest taps were performed. His appetite became poor, and he lost considerable weight. One week before admission he suddenly developed a severe and persistent headache involving the right side of the head, with blurring of vision in the right eye and some weakness of the extremities on the left.

A further history revealed that a younger brother had had symptoms similar to those of the patient, including moderate enlargement of the heart, with auricular fibrillation, and hepatosplenomegaly. Physical examination showed a wasted man, with a large protuberant abdomen. There was no evidence of facial asymmetry. The neck veins were distended and pulsating. The heart and lung findings were essentially unchanged. The liver was felt five to six fingerbreadths below the costal margin, and there was questionable pulsation. The spleen was easily palpable. Marked pitting edema of the lower extremities was present, more so on the left. The left arm and leg were weaker than those on the right, the left abdominal reflexes were absent, and there were positive Babinski and Chaddock signs on the left.

The temperature was normal, and the pulse continued to range about 60. The blood pressure was unchanged.

DR. BURWELL: An initial spinal-fluid pressure of 290 mm. of water is not significant of what is going on in the central nervous system unless we know the venous pressure, because the former rises precisely with the latter.

FURTHER DISCUSSION

This man had three things: a continuation of heart failure, pain in the right shoulder, elbow and fingers and over the precordial incision and some sort of intracranial accident that involved the motor tract on the right and caused a defect in the visual field of the right eye. The only way I can put these together as an alternative to the pericarditis that he did not have is in terms of vascular disease with thrombosis. He had a brother who had had similar symptoms. It was certainly not Wilson's disease. I do not find any way of explaining the cardiac situation on a neoplastic basis; we are fairly sure that he did not have a neoplasm of the pericardium, and there is no reason to think that he had an intracardiac neoplasm. Intracardiac neoplasm tends to be more progressive than this. I am inclined to believe that both the heart failure and the later symptoms were vascular in origin.

DR. CASTLEMAN: By that do you mean infarction of the myocardium?

DR. BURWELL: I mean old infarction of the myocardium, probably multiple ones, with a degenerated myocardium based on cardiac disease (myomalacia).

DR. HOLMES: It may be of help to look at the later films. The heart has not changed in size or shape during the interval, but the patient has developed fluid in the right pleural space as well as in the left. The pleural fluid is persistent.

DR. BURWELL: It certainly is persistent. There is no evidence of an infectious process that would satisfy me. I find it difficult to diagnose tuberculosis of the pleura. The patient had had fluid in the pleura for many years, and that is not the way an active tuberculous lesion of the pleura is apt to do. The possibility of neoplasm in any queer situation is always good. He had a low serum protein, which means that fluid would pour out into the pleural cavity with great ease from slight inflammation or from slight elevation of the venous pressure. I am trying to think of a good alternative in terms of a noncardiac situation in his pleura, but he had so much evidence of injury to the heart in the electrocardiogram and in the size of the heart that I am inclined to believe that the edema, the pleural effusion and the dyspnea on exertion were cardiovascular in origin. I do not believe that he had beriberi, and there is no reason to believe that he had an aortic dissection. I doubt that the queer kinds of heart disease, such as scleroderma, play any role here. I am afraid I cannot do better.

DR. J. H. MEANS: Could he have had a process, not constrictive pericarditis, that constricted the inferior vena cava?

DR. BURWELL: That is an attractive suggestion, but such cases are extremely rare. This man had a high venous pressure in the arms; he should therefore have had something wrong with his heart rather than a localized difficulty.

DR. WHITE: Yes; isolated constriction of the inferior vena cava would protect the heart and prevent an increase in the venous pressure in the arms and neck. It would give a big liver, of course.

DR. MEANS: Was there a mediastinal process?

DR. BURWELL: That is what I was thinking of, an intracardiac tumor where the cava enters, thus plugging up the auricles. I should think that the heart would be smaller, underworked rather than overworked.

DR. WHITE: May I summarize the situation as I recall it? We had Dr. Burwell come down here to see this man because we were frankly puzzled. The patient did not run true to form respecting chronic constrictive pericarditis, but we thought it only right to explore and Dr. Burwell agreed.

After the operation I entered the following note:

This patient's condition in all its details is unique in our experience, although it resembles somewhat that of one other patient, in that right ventricular enlargement, dilatation and failure are present, unexplained by history, symptoms, signs, laboratory data or even operation. Whether myocarditis, toxic or infectious, or a bizarre

coronary heart disease involving primarily the auricles and right ventricle is the etiologic factor we have no way of determining. Certainly the treatment should consist of tonic therapy for the heart and diuretic therapy for the congestion. It is conceivable that, with time and the subsidence, spontaneous or otherwise, of the toxic or infectious factor, the right ventricle may regain its tone, but it probably will not do so.

When the patient came to us at the time of the last admission we still had no answer concerning the underlying etiologic factor in his case. I wrote:

It is possible that a constitutional disease, as suggested by Dr. William Beckman, — for example, dermatomyositis involving the myocardium as well as the other muscles of the body, — may be the answer, but it is simply conjectural at present. I favor further studies along this line. The patient feels a little better.

It was because of Dr. Beckman's suggestion that a muscle biopsy was done. This gave negative results.

DR. BURWELL: Constitutional disease is a good idea, but I should be inclined to think that a man of forty-three who had thick vessels and absent pulsations in the feet, with subsequent hemiplegia, would be likelier to have a vascular disorder, either a precocious form of arteriosclerosis or polyarteritis. The story certainly does not sound like polyarteritis, although that is possible.

DR. WHITE: Do you think that the cerebral lesion might have been the result of embolism?

DR. BURWELL: Yes, it could have been; but I find little evidence for subacute endocarditis. If he had an embolus, it must have come from a mural thrombus.

DR. MEANS: Does periarteritis nodosa produce anything like this?

DR. CASTLEMAN: It can mimic anything.

DR. BURWELL: There is one other point regarding constitutional disease. The patient had a reasonably low white-cell count with a high percentage of monocytes, and perhaps one ought to think of some more active form of tuberculosis. But I do not see any other good evidence of active tuberculosis and am inclined to think that all his difficulties were on a vascular basis. I do not believe that he had syphilis.

CLINICAL DIAGNOSES

Cardiac hypertrophy, cause unknown.

Congestive failure.

Acute pulmonary edema.

DR. BURWELL'S DIAGNOSIS

Myocardial degeneration based on vascular disease.

ANATOMICAL DIAGNOSIS

Interstitial myocarditis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed a terminal bronchopneumonia and rather severe edema of the

lungs; there was also some fluid in both pleural cavities. The heart was enlarged but not markedly so; this was due mostly to dilatation rather than to hypertrophy. Since the heart weighed only 340

FIGURE 2. Photomicrograph of Heart Muscle.

gm., some might consider it to be at the upper limit of normal. The dilatation was equal in both the right and left chambers. The valves were negative. The coronary arteries were smooth, pliable and widely patent, and showed only a few atheromatous plaques. A small mural thrombus was found in the left auricular appendage, but no thrombi were detected in the other chambers of the heart. The heart itself was quite flabby, and the myocardium of both the right and left ventricles was rather gray in color, especially the trabeculae carneae and some of the papillary muscles. The liver was small, weighing only 1100 gm., and showed no evidence of cirrhosis. The spleen was small, weighing 160 gm., and contained two or three healed infarcts; it is quite possible that at one time the spleen was larger. One of the kidneys also had several healed infarcts.

Sections of the heart showed microscopically an unusual condition, which I am at a loss to explain. There was a diffuse interstitial fibrous myocarditis, involving both the right and left chambers but slightly more marked on the right (Figs. 2 and 3). Fibrous connective tissue had replaced a large amount of heart muscle, but its presence around in-

FIGURE 3. Photomicrograph of Heart Muscle (higher magnification).

cases of serious myocardial involvement following influenza or other virus diseases.

Dr. CASTLEMAN: Any acute infection that he had years ago that involved the myocardium could have produced this picture in the healed stage.

Dr. BURWELL: The patient did not have vascular disease. The arteries were fairly good. The absent

dividual bundles and its widespread distribution are quite unlike the scarring due to coronary insufficiency. It is not Fiedler's myocarditis because there is no cellular infiltration. Neither the large vessels nor the small arterioles showed any change. Beriberi or another type of vitamin deficiency seems unlikely. He had had the disease a long time, and I believe that he had had an adequate diet. We made a number of sections of various muscles of the body, all of which were normal. We thought seriously of dermatomyositis involving the myocardium. I suppose all one can call this is interstitial myocarditis, type undetermined.

Dr. BURWELL: The patient did not have the circulatory picture of beriberi, low pulse pressure, a low circulation time, and no complications to go with it.

Dr. WHITE: Could this be a residual from some such condition as was found in a case I discussed at a recent clinicopathological conference at the Peter Bent Brigham, a case of fatal influenzal myocarditis? Such is doubtless rare when of high degree, but it is possible that we are failing to recognize a few

pulsations in the feet were not borne out by anything that was found.

DR. CASTLEMAN: The aorta was normal.

DR. WHITE: In a recent article, Levy and von Glahn,⁶ of New York City, review a series of cases of myocardial disease of unknown cause. There are certain aspects of this case of ours that are somewhat similar to those of some of their group.

DR. MEANS: Dr. Castleman said that our patient had no hypertrophy.

DR. CASTLEMAN: I doubt that it fits in their group. I should rather believe that it was a deficiency affair or the end result of an acute infection years ago.

DR. MEANS: What about diphtheria? Does that end up with anything of this sort?

DR. CASTLEMAN: I believe that the myocarditis would be more spotty.

DR. BURWELL: What did you find in the brain?

DR. CASTLEMAN: Nothing was observed grossly or microscopically.

DR. WHITE: A word about the electrocardiogram. The low voltage of all the complexes in the limb leads is the most extreme that I have ever seen. The chest leads also indicate widespread myocardial disease.

THE STRAYER SURVEY AS IT CONCERNS
SCHOOL HEALTH IN BOSTON

The recently published Strayer survey of the Boston public schools is having its repercussions, and it is to be hoped that some definite improvements may be accomplished before the echoes die away. Surveys in themselves are excellent, but they are chiefly fact-finding and oblivion is their usual fate unless some agency or agencies take on the responsibility of following through with the recommendations.

Physicians should be particularly interested in the section of the report that deals with health services and health and physical education, and its criticism of health education has already received

Three main faults, in particular, are to be found with health instruction in the Boston schools, but these three are fundamental. According to the report, "The teachers are not trained in this subject, or only partly trained, or in some cases badly trained; textbooks and other vital teaching aids are lacking; and there is no adequate curriculum." Health service, as another factor in health education, although furnished by competent physicians and a staff of excellent nurses, with an advisory committee of high caliber, suffers from overdetailed legal prescriptions and inferior physical equipment. All health-service activity is authorized by law: the school physicians, for example, are required separately and carefully to examine every child in their respective districts at least once in every school year and to send a written notice of any defect or disability requiring treatment to the parent or guardian. The result is a burden of rapidly performed and superficial annual physical examinations, whereas careful examinations performed once in three years would be of incalculably greater value. The present system may be considered to be antiquated and inadequate.

The functions and purposes of physical education

are largely misunderstood. Thus, in a school document presenting a course in physical education it is stated that the purpose is to "provide an invigorating change from seat work." Four basic functions of physical education are given: to ensure the whole-some development of the vital organs of children; to teach functional skills; to develop and maintain an interest in various forms of motor activity; and to assist in the development of standard ways of behaving. Physical educators enjoy the reputation of having an aggressive attitude toward life, and in various instances have assumed or have been given the responsibility for health instruction, for which they are not trained, in addition to that for physical education.

Trained personnel, nevertheless, stands out as the greatest need in health instruction. The duty

*Editorial. Health education in Boston schools. J. A. M. A. 126.1086, 1944.

usually falls to the lot of the room teacher. If she is not trained for this part of her job, it is up to the teachers' colleges of this health-minded nation to see that teachers of the future are so trained, just as it should be the responsibility of the medical schools to see that medical students are taught to understand and appreciate the duty that medicine owes to the school child.

In Massachusetts, well-organized and well-staffed state departments of Health and of Education have been engaged in the mutual enterprise of offering constructive health-education programs for the cities, towns and villages outside of Boston that care to participate. A joint committee in 1941 and 1942 made a study of health instruction in the secondary schools, and a relatively permanent joint steering committee has prepared courses of study for the various grades. The departments function largely in an advisory capacity and have, unfortunately, had difficulty in obtaining sufficient funds from the Commission on Administration and Finance to carry on these activities. The revised *Guide to School Health*, for instance, went to the commission on August 23, 1944, but as yet no action has been taken.

Boston, although in some ways a part of the Commonwealth, does not recognize its good offices, being a law unto itself. If Boston is considered the right hand of the Commonwealth, and the state outside Boston the left hand, then the right hand knoweth not what the left hand doeth, although the left hand doeth very well in many matters. Were it not too much *infra dignitatem*, the capital city might benefit from a scrutiny of these departments' activities.

THE MEDICAL CLASSIFICATION SCHEME OF THE BOSTON MEDICAL LIBRARY

SOON after the Boston Medical Library was organized on August 20, 1875, with Dr. Oliver Wendell Holmes as president and Dr. James R. Chadwick as librarian, two rooms on the first floor of No. 5 Hamilton Place were fitted up as a library, under the charge of Dr. Edwin H. Brigham as assistant librarian. A scheme of classification of books and pamphlets was quickly adopted, only to

be remodeled four years later by Dr. Chadwick, ably assisted by Mrs. Elizabeth J. Collins, the cataloguer. The new model was based, with important modifications, on the *Index Medicus*, a monthly classified record of the current medical literature of the world compiled under the supervision of Drs. J. S. Billings and Robert Fletcher at the Army Medical Library in Washington. Indeed, at the same time that Dr. Billings was at work, with Dr. Fletcher, on the first volume of the *Index-Catalogue of the Library of The Surgeon-General's Office, United States Army*, Dr. Chadwick, in Boston, was reading proof for Dr. Billings of that vast compilation. Thus, medical classification was much in the minds of these ardent gentlemen and the Boston Medical Library was well in the forefront of a rapidly evolving subject.

As years went on, further changes were needed in the Boston scheme and this work was undertaken by James F. Ballard, then and now the director of the Boston Medical Library. The value of the Boston classification was soon recognized, particularly after it had been published in the January, 1918, issue of the *Bulletin of the Medical Library Association*.¹ The plan was soon adopted as the official classification scheme of the Medical Library Association and was recommended for use in medical libraries, particularly new ones.

The Boston Medical Library classification is now used in all the medical schools and hospitals of Boston and in many medical libraries throughout the world. Over seven hundred copies of a second edition,² published in 1925, were sold, thus testifying to the usefulness of this classified plan. A new revision has recently been issued, with a few additions.³ The scheme is remarkably simple and easy to expand, and has become the most popular for medical-library use. It has been adopted by the libraries of the Cleveland Medical Association, the Mayo Clinic, the Peking Union Medical College and the Colorado University School of Medicine and many others.

The chief disadvantage of the Boston Medical Library scheme has been its infrequent revision, with lack of sufficient expansion in certain sections. These criticisms have been met in the 1944 edition, and in addition to the usual schedules, Mr. Ballard

a woman whom I saw recently gave a history of ragweed-pollen hay fever of five seasons' duration. Because of nasal congestion she purchased a bottle of Privine over the counter at her local drugstore on September 16, 1944. This part of the first time, she did not experience the usual relief of hay-fever symptoms with the coming of frost. It is interesting to note that since she first started to use Privine

DR. POLLOCK RETIRES

Dr. Henry M. Pollock retired on February 1, after thirty years as superintendent of the Massachusetts Memorial Hospital. Dr. Pollock had been a hospital administrator for

Hospitals after eleven years of successful administration at the Norwich State Hospital. The enviable reputation made in Norwich continued during his superintendency at the

Massachusetts Memorial Hospitals. Besides many innovations and improvements in all departments, he was largely responsible for the addition of two new buildings to the plant. He was a constant crusader for the elevation and maintenance of medical standards, education and practice. His

activities in the hospital field include many years as associate commissioner of the Department of Mental Diseases (now the Department of Mental Health); he was a trustee of the American Hospital Association for six years and is nationally known as a consultant in hospital planning and construction. Dr. Pollock is succeeded by Dr. Leverett S. Woodward, formerly associate director of the Harper Hospital in Detroit.

and secretary of the Greater Detroit Hospital Council.

DELETERIOUS EFFECTS OF PRIVINE HYDROCHLORIDE

To the Editor: Privity hydrochloride, as 0.10 and 0.05 per

cent solutions, was introduced in 1947 as a nasal vasoconstrictor. The advantages claimed for Privine were prolonged vasoconstriction, small dosage and physiologic rationale. The dose of Privine is two to three drops nasally, and it produces symptomatic relief from the nasal congestion for two to six hours. Since it is prepared in isotonic solution buffered to the same pH as that of the "cellular nasal mucosa membranes," it was said to be nonirritating; furthermore, it was claimed that it restores the alkaline pH range of the nasal mucosa to the normal acid range.

During the last year, I sensed the fact that more and more patients were becoming chronic users of Rhine and began reactions superimposed on the coriza of day, fever or definite exacerbations such as sinusitis or otitis. These patients generally gave a similar story. "Rhine was prescribed either for a 'head cold' or for some form of allergic coriza. At the beginning they found that one or two drops of Rhine installed nasally gave excellent relief for two to six hours. In fact the majority thought that this was the best nose drop they had ever used. As the patients continued to use the medication, however, they found that the nasal congestion would not recur as often as they had hoped. Some soon began to believe that the drop could not be used along with the use of Rhine and would take out a vial to show that they kept it with them as all these things.

A frequent observation following the use of Pristine for hay fever was the continuance of symptoms far beyond the pollinating season. This was most unusual and was commented on by a number of "Pristine addicts." In many cases the Pristine had not been prescribed by a physician. For example

MISCELLANY

DR. POLLOCK RETIRES

Dr. Henry M. Pollock retired on February 1, after thirty years as superintendent of the Massachusetts Memorial Hospitals.

Dr. Pollock had been a hospital administrator for forty-six years, having come to the Massachusetts Memorial Hospitals after eleven years of successful administration at the Norwich State Hospital. The enviable reputation made in Norwich continued during his superintendency at the Massachusetts Memorial Hospitals. Besides many innovations and improvements in all departments, he was largely responsible for the addition of two new buildings to the plant. He was a constant crusader for the elevation and maintenance of medical standards, education and practice. His activities in the hospital field include many years as associate commissioner of the Department of Mental Diseases (now the Department of Mental Health); he was a trustee of the American Hospital Association for six years and is nationally known as a consultant in hospital planning and construction.

Dr. Pollock is succeeded by Dr. Leverett S. Woodworth, formerly associate director of the Harper Hospital in Detroit, president of the Michigan Hospital Association and a trustee and secretary of the Greater Detroit Hospital Council.

CORRESPONDENCE

DELETERIOUS EFFECTS OF PRIVINE HYDROCHLORIDE

To the Editor: Pristine hydrochloride, as 0.10 and 0.05 per cent solutions, was introduced in 1942 as a nasal vasoconstrictor. The advantages claimed for Pristine were prolonged vasoconstriction, small dosage and physiologic rationale. The dose of Pristine is two to three drops nasally, for two to six hours. Since it is prepared in isotonic solution buffered to the same pH as that of the "delicate nasal mucous membranes," it was said to be nonirritating; furthermore, it was claimed that it restores the alkaline pathologic secretions to the normal acid range.

Almost overnight Pristine became the popular nose drop. During the last year, I sensed the fact that more and more patients were becoming chronic users of Pristine and began to see a number of patients who had either marked vasomotor reactions superimposed on the coryza of hay fever or definite exacerbations of symptoms in cases of typical hyperplastic vasomotor rhinitis. These patients generally gave a similar story. Pristine was prescribed either for a "head cold" or for some form of allergic coryza. At the beginning they found that one to two drops of Pristine instilled nasally gave excellent relief for two to six hours. In fact the majority thought that this was the finest nose drop they had ever used. As the patients continued to use the medication, however, they found that the nasal congestion began to recur as often as every one or two hours. Some soon began to believe that they could not get along without the use of Pristine and would take out a vital to show that they kept it with them at all times.

A frequent observation following the use of Pristine for hay fever was the continuance of symptoms far beyond the pollinating season. This was most unusual and was commented on by a number of "Pristine addicts." In many cases the Pristine had not been prescribed by a physician. For example

STANDARDS OF MEDICAL EDUCATION

To the Editor: I have read with interest the editorial "Standards of Medical Education," which appeared in the February 1 issue of the *Journal*. May I comment on it, as it shows some lacunae which the medical profession may wish to have filled, and some errors in statement of fact which, while not of vital import, should be corrected in the interests of accuracy.

The editorial does not do justice to the Approving Authority in saying that "the failure of the Massachusetts Approving Authority to accredit the Middlesex University School of Medicine was upheld by the Superior Court of Suffolk County." The failure on the part of the Approving Authority, if there was any failure, would be in the procedure leading to the actual decision and not in the omission of a decision, as the writer of the editorial implies. A definite decision was made, with full knowledge that the decision meant, as far as the Approving Authority was concerned, that a medical school which had been growing vigorously and improving itself rapidly, with a faculty and students, and with property and equipment estimated at one and a quarter million dollars, took value, would be closed at a time when the national need for more physicians is urgent.

The meaning of the personal references in the editorial is not entirely clear, but in the spring of 1935 the secretary of the Massachusetts Medical Society informed me as secretary of the Board of Registration in Medicine that the president of the Society, a past-president and he himself, having been advised by a high political authority, were opposed to the introduction, for the 1936 session of the Legislature, of a bill to exercise some control over medical education, and he urged that no bill be introduced. The matter was considered by the Board at one of its meetings, and, notwithstanding the objection by the officers of the Society, the Board introduced a bill which, however, cannot be recognized in the Act of 1936.

Reference is made in the editorial to Middlesex University and "three inspections." It is worthy of note that after the first inspection, in 1941, there were six points, out of a possible seventeen, against the school; after the second, in 1943, there were five; after the third, in 1944, there were four; and after Judge Cabot's decision there were three. If in three years the school removed 50 per cent of its deficiencies, why was it "necessary for the present Approving Authority to deny approval"? This is a pertinent question for which a public answer by the Approving Authority would not be out of place. The chairman of the Approving Authority is reported to have said that he did everything that he could for the school, that the Approving Authority had no discretion and that it had to act in accordance with the law. Accepting the first statement at its face value, and the third statement as

I believe that Pristine should never be used for longer than four to five days and then only when the patient is under the care of a physician. Furthermore, something should be done about the indiscriminate sale of Pristine over the drug-store counter.

320 Beacon Street
Boston 15
IRVING W. SCHILLER, M.D.

obvious, there remains to be discussed, first, what the law does or does not say, and second, what the law does or does not mean. I can only touch on some of these points.

At least three defects of the law are evident at once. As Judge Cabot said, "The statute lays down neither for the Approving Authority nor this court any guide by which approval should be granted or withheld."

A second defect is that if approval is once given, it cannot be taken away. No matter how much the school may deteriorate, the Approving Authority can only sit by and let it go downhill, with approval. This would put the Approving Authority in a ridiculous position.

A third defect is that if a school meets the requirements 90 per cent, the law provides for no status intermediate between approved and not approved. Such status does in fact exist, namely, "on probation," although it is not recognized by the statute. In the requirements for approval drawn up by the Approving Authority in 1936, an attempted make-shift for the solution of the problem caused by this defect was introduced by using the word "adequate" in eight of the seventeen requirements. A school may be adequate in giving a good medical education, although inadequate in one or more of its departments. Few schools satisfy even themselves in every respect.

When the question was raised as to whether the make-shift solution would be satisfactory, a bill was introduced before the Legislature to cover this very point but it was not enacted. Yet right here is perhaps the most serious defect in a very defective law.

The writer of the editorial is too optimistic in saying "At long last the practice of medicine in the Commonwealth is open only to the men and women who have been properly trained and Massachusetts need no longer be called 'the dumping ground for medical-school graduates'." Apparently a clerical error has slipped in here as since about 1914, only medical-school graduates have been admitted to examination. But the writer has forgotten that every physician who matriculated in a medical school before January 1, 1941, no matter how long before, is eligible for admission to examination, even if the medical school from which he graduated has never been approved.

On the other hand, the writer of the editorial is too pessimistic. Referring to bills now before the Legislature, he says, "The passage of such legislation can either halt or stop forever the progress toward higher medical standards." "Forever" is a long time. Does he think that the General Court of Massachusetts can, in 1945, take any action that will last forever? Then he goes on to say, "and high standards of medical education *must* be maintained in these days when the practice of medicine is being subjected to criticism." *Must* they be maintained? Let him see the Army about that and then talk with some of the persons in medical education who are vocal on this subject, such as Dean Branch, Dr. Everts Graham, Dr. Victor Johnson, Dean MacEwen, Dean Rappleye and Dr. Joseph Wear, and see if what *must* be done *has* been done.

The many defects of the Act of 1936, Chapter 247, I shall take up at another time, for they are serious and should be remedied. Some of the hills which have been introduced incorporate suggestions for improvement. There is needed a discriminating understanding of what the situation demands. We are in the transition period of a reform, and every reform presents the possibility of at least two dangers — first, from fanatical reformers who ruthlessly seek the desired end without regard for the harm they may do on the way, and second, from the self-seeking who may profit from the reform and to whom justice is meaningless as applied to persons other than themselves. Against both dangers we should be on guard now.

STEPHEN RUSHMORE

520 Commonwealth Avenue
Boston

* * *

The *Journal* is primarily interested in the improvement of standards of medical education in Massachusetts, rather than whether or not this or that medical school should be accredited. Few will deny that in 1936, by virtue of its inadequate medical-practice act, the Commonwealth had become a "dumping ground for the graduates" of non-approved medical schools. Certainly those who are responsible for the health of the people should undergo a course of

training that meets certain minimum standards, and the creation of the Approving Authority was a step in the proper direction. It is to be hoped that future legislation will continue forward rather than turn backward. — Ed.

NOTICES

NORTON MEDICAL AWARD FOR 1946

The Norton Medical Award, which is offered annually by W. W. Norton and Company, Incorporated, to encourage the writing of books on medicine and the medical profession for the layman, totals \$3500 (\$1000 outright and the balance an advance against royalties). The author must be a professional worker in the field of medicine, or a collaborator with such a person. The final date for submission of manuscripts is December 1, 1945. Further details are contained in a descriptive circular that may be obtained from W. W. Norton and Company, Incorporated, 70 Fifth Avenue, New York 11, New York.

BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held in the Main Lecture Room of the Harvard Biological Laboratories on Wednesday, March 21, at 8 p.m.

PROGRAM

- Estrogen Metabolism in Women. Drs. O. W. Smith and G. Van S. Smith.
- Vitamins in Relation to Skeleton Growth. Dr. S. B. Wolbach.
- Chorionic Luteotropin and Luteal Function in Monkeys. Dr. F. S. Hisaw.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Wednesday, March 21, at 8:15 p.m. Dr. Philip Levine will speak on the subject "The Clinical Significance of the Rh Factor." A discussion by Drs. Benjamin Alexander, William Dameshek and Karl Singer will follow.

NEW YORK INSTITUTE OF CLINICAL ORAL PATHOLOGY

The New York Institute of Clinical Oral Pathology will hold an open meeting at the New York Academy of Medicine, 2 East 103rd Street, New York City, on Monday, April 30, at 8:15 p.m. A symposium entitled "A Survey of the Antihiotic Problem" will be presented. The program is as follows:

- The Role of Biotics and Antihiotics in Chemotherapy. Dr. Daniel Laszlo.
- The Problem of Penicillin in Treatment of Mixed Infections. Dr. Frank Lamont Meleney.
- The Treatment of Acute and Chronic Infections of the Jaws with Antibiotics. Dr. Leo Stern.
- The Relative Value of Antihiotics in the Treatment of Otolaryngic Diseases. Lt. Col. Kenneth M. Kahn.
- Evaluation of Antihiotic Agents for Root Canal Treatment. Dr. Louis I. Grossman.
- The Role of Iontophoresis in Ocular Therapy with Antibiotics. Dr. Ludwig von Sallmann.
- Treatment of Ulcerative Stomatitis (Vincent's Infection) with Penicillin. Dr. Alvin E. Strock.

For further information all communications should be addressed to G. Roistacher, Executive Secretary, 101 East 79th Street, New York 21, New York.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MARCH 22

FRIDAY, MARCH 23

- *9:00-10:00 a.m. Some Aspects of Cardiac Surgery. Dr. Robert E. Gross. Joseph H. Pratt Diagnostic Hospital.

THE TREATMENT OF URETERS INJURED DURING GYNECOLOGIC OPERATIONS

FRANCIS M. INGERSOLL, M.D.,* AND JOE V. MEIGS, M.D.†

BOSTON

ACCIDENTAL injury of a ureter is the most frequent serious complication of gynecologic pelvic operations. This fact was brought to our attention by the occurrence of 7 ureteral injuries in 590 total hysterectomies and 1 ureteral injury in 170 supravaginal hysterectomies done during a five-year period at the Massachusetts General Hospital. These 8 cases will serve to illustrate the type of injuries that occur and the surgical principles and procedures to be followed in repairing them.

PRINCIPLES OF TREATMENT

Although each patient must be treated according to the circumstances of the case, there are certain important principles that should be observed when dealing with the problem of the damaged ureter. First, the immediate recognition of the injury is of the utmost importance. This is especially true since proper treatment at the time of operation may result in a successful anastomosis, with hospitalization no longer than that required for the routine uncomplicated procedure. In the 8 cases reviewed herein, injury was noted at time of operation in 4. Three of these patients did well; the fourth developed a urinary fistula and a pelvic abscess and later came to nephrectomy. Secondly, every effort should be made to preserve the kidney function on the side of the injured ureter until the function of the other side can be determined. Partial is not an adequate means of determining renal function, and the sacrifice of a kidney by ligation or nephrectomy without knowledge of the status of the remaining kidney is unwise. Preservation of the kidney may be accomplished by nephrotomy, skin ureterostomy or transplantation of the ureter into the bowel or bladder. The technique of such transplantation will be discussed later. The third important principle is that all ureteral anastomosis should be done over an indwelling nylon or rubber ureteral catheter. The catheter serves as a splint during the healing of the ureter and also

Following the principle of repair at the time of the operation, an end-to-end anastomosis is indicated. The injured portion of the ureter is excised, and the two ends of the ureter are freed to provide adequate material, both proximally and distally, with which to work. A nylon ureteral catheter is introduced up to the kidney pelvis and the distal end is placed in the bladder. The catheter should be partially drawn out during cystoscopy at the end of the operation and attached to the thigh. The two ends of the cut ureter are approximated by suturing them around the catheter by the use of mattress sutures of fine silk, cotton or catgut. The area of the anastomosis is drained retroperitoneally through a stab wound in the flank by means of an empty Miller wick.

The Incised or Ligated Ureter

TREATMENT AT TIME OF INJURY

acts to decompress the kidney pelvis, preventing distention at the site of the anastomosis. The indwelling catheter has proved itself to be the most vital single factor in successful anastomosis. It should remain in place for seven or eight days after operation.

Three of the 8 cases illustrate the treatment of the incised or ligated ureter. These are reported below

Miller wick.

Bump and Crowe¹ in 1929 reported on their experience with end-to-end ureteral anastomoses in dogs. They anastomosed over one catheter and decompressed the proximal ureter with another brought out through a stab wound in the flank. Without the catheters their anastomoses resulted in fistulas and -hydromephrrosis. Curtis² in 1929 reported a case with successful anastomosis by this method. Dr. Fletcher H. Colby, in a personal communication, has advised a proximal decompression of the ureter with a small rubber catheter, omitting the inflying ureteral catheter. Proximal decompression has not been used in our cases.

Following the principle of repair at the time of the operation, an end-to-end anastomosis is indicated. The injured portion of the ureter is excised, and the two ends of the ureter are freed to provide adequate material, both proximally and distally, with which to work. A nylon ureteral catheter is introduced up to the kidney pelvis and the distal end is placed in the bladder. The catheter should be partially drawn out during cystoscopy at the end of the operation and attached to the thigh. The two ends of the cut ureter are approximated by suturing them around the catheter by the use of mattress sutures of fine silk, cotton or catgut. The area of the anastomosis is drained retroperitoneally through a stab wound in the flank by means of an empty

Case 1. G. P., a 47-year-old quartipara, had a fibroid uterus that had grown two thirds of the way to the umbilicus. At operation hemorrhage occurred from varices in the left broad ligament, and the ureter was clamped and cut 12 cm.

from the bladder. Both ends of the ureter were freed and anastomosed end to end over a ureteral catheter. Five mattress sutures of silk were used. The area of the anastomosis was drained through a stab wound in the flank. The catheter came out on the 4th day, and urine drained from the flank wound for 6 days. A slight hydronephrosis was demonstrated by intravenous pyelogram but later disappeared. An intravenous pyelogram 1 year later was normal.

CASE 2. E. D., a 47-year-old primipara, had endometriosis involving the ovaries and the posterior cul-de-sac. The left ureter was injured as the uterine vessels were being tied during the course of a total hysterectomy and bilateral salpingo-oophorectomy. A sleeve type of anastomosis was done over an inlying catheter, the distal end being placed inside the proximal end and secured by arterial silk. The area was drained by an empty Miller wick through a stab wound in the flank. The catheter came out on the 4th day, resulting in a ureterovaginal fistula, which healed in 17 days. At that time a marked hydronephrosis was demonstrated by intravenous pyelogram, but within 6 weeks an intravenous pyelogram was normal.

CASE 3. E. D., a 41-year-old, unmarried woman, had a fibroid tumor the size of a 7-month pregnancy. During the hysterectomy the left ureter was ligated when the uterosacral ligaments were clamped and cut. The damaged ureter was freed, and the ligature removed. After the uterus had been removed a sleeve type of anastomosis was done, the distal end of the ureter being placed inside the proximal end and held in place with three No. 00 chromic-catgut stitches. A cuff of peritoneum was sutured around the site of the anastomosis. The area was drained retroperitoneally, the wick being brought out through the left flank. A ureteral catheter was not used. Urine drained copiously from the stab wound for 2 weeks. During the 3rd week after operation a large abscess, accompanied by pyelonephritis with chills and fever, developed in the left lower quadrant of the abdomen. Re-exploration 7 weeks later demonstrated that the upper end of the left ureter ended in the abscess cavity; the distal section was not identified. A left nephrectomy was performed, recovery from which was uneventful.

Comment. This case, the only one of the 3 reported that was done without a ureteral catheter, demonstrates the dangers and difficulties encountered when a ureteral catheter is not used.

The Resected Ureter

Repair of the resected ureter is a problem. End-to-end anastomosis is usually impossible, so that one of the following methods must be used: ureterovesical transplant, ureterosigmoidal anastomosis, skin ureterostomy or ligation of the distal and proximal ends of the ureter. Nephrectomy must occasionally be resorted to.

Ureterovesical transplant. Ureterovesical transplant is the most satisfactory procedure. The cut end of the ureter is freed, the bladder is mobilized, and the free end is measured against the site of implantation to make certain that suturing is possible without tension on the ureter. To avoid strain resulting from bladder distention, a site as low as possible on the bladder should be chosen. An incision through the detrusor muscle and mucosa is made, and the ureter, which has been split for suturing, is brought through it into the bladder. The two flaps are then sutured to the bladder mucosa and the bladder muscle is closed about the ureter, one of the stitches catching the adventitia to help hold it in place. The bladder wall is then drawn about the ureter in such a way as to afford an oblique entrance into the bladder. The operative site is drained with

a Penrose drain. Bladder distention is avoided by using a suprapubic drain or an indwelling urethral catheter for as long as ten days following operation. This is a safe procedure if the ureter will reach the bladder without tension.

Ureterosigmoidal anastomosis. If the resection of the ureter has been high, ureterosigmoidal anastomosis may be indicated. This method of preserving kidney function is a difficult technical procedure and is frequently complicated by sepsis. It should not be attempted by the inexperienced surgeon, since skin ureterostomy is safer.

The technic of ureterosigmoidal anastomosis was standardized by Coffey³ in 1928. There are many modifications of his method, but his principle of a valvelike action on the ureteral wall as it passes tangentially through the bowel wall is the important technical feature of the operation. The ureter is exposed and the sigmoid is brought over to it, the site of implantation being as low in the bowel as possible without tension. An incision 4 cm. long is made through the serosa of the bowel and through the muscularis to the submucosa, the latter being stripped from the muscularis over a small area so that the ureter will have a place to lie. The segment of bowel is clamped above and below with rubber-covered clamps. A tiny incision is made in the mucosa with a cautery at the lower end of the prepared area. A stitch is attached to the free end of the ureter, and the needle is passed through the mucosal incision along a grooved director. The needle and stitch are brought out through the bowel wall, and by traction the ureter is pulled within the sigmoid. The ureter is held by placing a stitch through the peritoneum and muscularis, which catches a small bit of ureteral wall. The muscularis and peritoneum are closed with interrupted catgut.

Skin ureterostomy. A simple procedure to preserve kidney function, and one that adds little to the operation, is skin ureterostomy. The sectioned ureter is freed above the injury. Care is taken to preserve the loose areola tissue around the ureter so as to maintain its blood supply. The lateral peritoneum is dissected free, and the ureter is brought out through a stab wound on the anterior abdominal wall at the level of and medial to the anterior superior spine. The ureter is not stitched to the peritoneum or fascia but is fastened to the skin.

Ligation of ureter. A fourth possibility in the care of resected ureter is ligation. If previous urologic studies have shown good function of both kidneys without infection, ligation is probably the quickest and easiest procedure, although the chance must be taken that aseptic necrosis will follow ligation. Barney⁴ in 1912 demonstrated experimentally that not all ligated ureters result in an aseptic necrosis. Hepler⁵ in 1940 found that 3 per cent of patients so treated died, 24 per cent developed urinary fistulas, and 15 per cent ultimately had to have nephrectomy. Peacock⁶ in 1941 reported a series of 8 patients so

treated, 2 of whom died as a result of fistula and sepsis. He advocates immediate nephrectomy, which may be safer than ligation.

The present series includes the following example of successful ligation.

Case 4. M. A., a 50-year-old bipara, was admitted because of an abdominal mass extending halfway to the umbilicus. At operation a large fibroid was found, with the left tube and ovary thinned out over the body of the tumor. The left ureter was in the posterior sheath of the broad ligament, and a large section was inadvertently excised. Both ends of the excised ureter were ligated and the total hysterectomy was completed. After operation the temperature rose daily to 101°F. but subsided on the 8th day. The urinary output was good. The nonprotein nitrogen rose to 44 mg. per 100 cc., but fell to 20 mg. on the 14th day. The patient was discharged on the 15th postoperative day and was well at follow-up 1 year later.

Recognition of ureteral injury after operation is a surgical as well as a urologic problem. The methods of meeting this complication should be known to both the surgeon and the gynecologist.

Bilateral ligation may be diagnosed by annuita and a rising nonprotein nitrogen. Cystoscopy demonstrates the blocked ureters. For this reason, the urinary output of gynecologic patients should be carefully followed. Prompt relief of bilateral ureteral obstruction is necessary, and nephrostomy is the quickest and safest procedure. This drains the blocked kidneys and relieves the patient over her acute difficulty. She can then be observed to see whether the catgut ties are dissolving, thus relieving the ureteral obstructions. Subsequent therapy depends on circumstances. Deligation may be attempted, but the operative mortality is high, and the risk of subjecting the patient to immediate post-operative re-exploration is unwarranted.

Injury to one ureter by ligature, unrecognized at the time of operation, is usually revealed by the development of a ureterovaginal fistula.

These fistulas ordinarily appear ten days to three weeks after operation. Some of them close spontaneously, and such an event should be awaited; failing this, treatment must be considered. Sub-sidence of local inflammatory processes around the site of the fistula is necessary, since an attempt to close it before resolution will be futile. In elderly women with a ureterovaginal fistula together with sepsis, nephrectomy, although sacrificing the kidney, is both quick and safe. The following case in this series was so treated successfully.

Case 5. C. G., a 63-year-old unmarried woman, developed a ureterovaginal fistula following hysterectomy for endometrial cancer. During operation it was necessary to stop bleeding from the left corner of the vagina by a figure-eight suture. The fistula, which was first noticed on the 8th postoperative day, failed to close of its own accord. Considering the patient's age, her disease and the fact that the other kidney functioned well, a nephrectomy was done. The convalescence was satisfactory, and the patient has remained well for the 2 years during which she had been followed by the Tumor Clinic.

Case 7. A. H., a 49-year-old nulliparous woman had had a supravaginal hysterectomy for the removal of a large fibroid in the right broad ligament. The operation was accomplished with some difficulty. A right ureterovaginal fistula developed on the 20th postoperative day, the block being 4 cm. from the ureteral orifice. Two months later, a ureterectomy was done, the dilated right ureter being implanted without undue tension. The convalescence was uneventful, and an intravenous pyelogram 4 months later showed good kidney function. Two years later the patient was still well.

Case 6. M. G., a 35-year-old nulliparous woman, had severe vaginal bleeding of 6 weeks' duration and an enlarged uterus. A total hysterectomy was done, and on the 15th postoperative day a fistula was noted and cystoscopy demonstrated a blocked ureter on the right side. One month later, exploration showed the right ureter to be involved in scar about 5 cm. from the bladder. A ureterovesical transplant was done and the bladder was drained suprapubically. After operation an intravenous pyelogram demonstrated a slight hydronephrosis on the right; this subsequently subsided, and the patient was well 4 years after operation.

Case 8. M. G., a 35-year-old nulliparous woman, had severe vaginal bleeding of 6 weeks' duration and an enlarged uterus. A total hysterectomy was done, and on the 15th postoperative day a fistula was noted and cystoscopy demonstrated a blocked ureter on the right side. One month later, exploration showed the right ureter to be involved in scar about 5 cm. from the bladder. A ureterovesical transplant was done and the bladder was drained suprapubically. After operation an intravenous pyelogram demonstrated a slight hydronephrosis on the right; this subsequently subsided, and the patient was well 4 years after operation.

Another reason for nephrectomy for ureterovaginal fistula was found in Case 3, discussed above. This patient's left ureter was anastomosed end to end—unsuccessfully. There was profuse drainage of urine through the stab wound and some vaginal drainage. A pelvic abscess formed and was drained through the stab wound. Seven weeks after operation the patient was still seriously ill. There was a marked hydronephrosis as demonstrated by intravenous pyelogram, and the temperature reached 104°F. daily. Re-exploration demonstrated that the left ureter ended in the abscess cavity; the distal end was not identified. A nephrectomy was done and the pelvic sepsis subsided. Recovery was rapid and uneventful, and the patient was free of symptoms at the end of three months.

Some ureterovaginal fistulas develop late and are accompanied by relatively little sepsis. In this event, exploration of the site of the ureteral injury is indicated, and ureterovesical transplantation is usually possible. This alternative is preferable to nephrectomy. Two cases, described below, were successfully treated in this manner.

There is still another type of injury not recognized at operation that should be mentioned, namely, the ligated ureter that does not cause a fistula. How many such cases there are is unknown. Newell¹⁷ in 1939 reported 15 cases of ureteral injury; 6 of these patients had unilateral ligations that were unsuspected until discovery at autopsy.

All patients who have a difficult time after operation should be watched for ureteral difficulties. Severe costovertebral pain may be caused by a

from the bladder. Both ends of the ureter were freed and anastomosed end to end over a ureteral catheter. Five mattress sutures of silk were used. The area of the anastomosis was drained through a stab wound in the flank. The catheter came out on the 4th day, and urine drained from the flank wound for 6 days. A slight hydronephrosis was demonstrated by intravenous pyelogram but later disappeared. An intravenous pyelogram 1 year later was normal.

CASE 2. E. D., a 47-year-old primipara, had endometriosis involving the ovaries and the posterior cul-de-sac. The left ureter was injured as the uterine vessels were being tied during the course of a total hysterectomy and bilateral salpingo-oophorectomy. A sleeve type of anastomosis was done over an inlying catheter, the distal end being placed inside the proximal end and secured by arterial silk. The area was drained by an empty Miller wick through a stab wound in the flank. The catheter came out on the 4th day, resulting in a ureterovaginal fistula, which healed in 17 days. At that time a marked hydronephrosis was demonstrated by intravenous pyelogram, but within 6 weeks an intravenous pyelogram was normal.

CASE 3. E. D., a 41-year-old, unmarried woman, had a fibroid tumor the size of a 7-month pregnancy. During the hysterectomy the left ureter was ligated when the uterosacral ligaments were clamped and cut. The damaged ureter was freed, and the ligature removed. After the uterus had been removed a sleeve type of anastomosis was done, the distal end of the ureter being placed inside the proximal end and held in place with three No. 00 chromic-catgut stitches. A cuff of peritoneum was sutured around the site of the anastomosis. The area was drained retroperitoneally, the wick being brought out through the left flank. A ureteral catheter was not used. Urine drained copiously from the stab wound for 2 weeks. During the 3rd week after operation a large abscess, accompanied by pyelonephritis with chills and fever, developed in the left lower quadrant of the abdomen. Re-exploration 7 weeks later demonstrated that the upper end of the left ureter ended in the abscess cavity; the distal section was not identified. A left nephrectomy was performed, recovery from which was uneventful.

Comment. This case, the only one of the 3 reported that was done without a ureteral catheter, demonstrates the dangers and difficulties encountered when a ureteral catheter is not used.

The Resected Ureter

Repair of the resected ureter is a problem. End-to-end anastomosis is usually impossible, so that one of the following methods must be used: ureterovesical transplant, ureterosigmoidal anastomosis, skin ureterostomy or ligation of the distal and proximal ends of the ureter. Nephrectomy must occasionally be resorted to.

Ureterovesical transplant. Ureterovesical transplant is the most satisfactory procedure. The cut end of the ureter is freed, the bladder is mobilized, and the free end is measured against the site of implantation to make certain that suturing is possible without tension on the ureter. To avoid strain resulting from bladder distention, a site as low as possible on the bladder should be chosen. An incision through the detrusor muscle and mucosa is made, and the ureter, which has been split for suturing, is brought through it into the bladder. The two flaps are then sutured to the bladder mucosa and the bladder muscle is closed about the ureter, one of the stitches catching the adventitia to help hold it in place. The bladder wall is then drawn about the ureter in such a way as to afford an oblique entrance into the bladder. The operative site is drained with

a Penrose drain. Bladder distention is avoided by using a suprapubic drain or an indwelling urethral catheter for as long as ten days following operation. This is a safe procedure if the ureter will reach the bladder without tension.

Ureterosigmoidal anastomosis. If the resection of the ureter has been high, ureterosigmoidal anastomosis may be indicated. This method of preserving kidney function is a difficult technical procedure and is frequently complicated by sepsis. It should not be attempted by the inexperienced surgeon, since skin ureterostomy is safer.

The technic of ureterosigmoidal anastomosis was standardized by Coffey³ in 1928. There are many modifications of his method, but his principle of a valvelike action on the ureteral wall as it passes tangentially through the bowel wall is the important technical feature of the operation. The ureter is exposed and the sigmoid is brought over to it, the site of implantation being as low in the bowel as possible without tension. An incision 4 cm. long is made through the serosa of the bowel and through the muscularis to the submucosa, the latter being stripped from the muscularis over a small area so that the ureter will have a place to lie. The segment of bowel is clamped above and below with rubber-covered clamps. A tiny incision is made in the mucosa with a cautery at the lower end of the prepared area. A stitch is attached to the free end of the ureter, and the needle is passed through the mucosal incision along a grooved director. The needle and stitch are brought out through the bowel wall, and by traction the ureter is pulled within the sigmoid. The ureter is held by placing a stitch through the peritoneum and muscularis, which catches a small bit of ureteral wall. The muscularis and peritoneum are closed with interrupted catgut.

Skin ureterostomy. A simple procedure to preserve kidney function, and one that adds little to the operation, is skin ureterostomy. The sectioned ureter is freed above the injury. Care is taken to preserve the loose areola tissue around the ureter so as to maintain its blood supply. The lateral peritoneum is dissected free, and the ureter is brought out through a stab wound on the anterior abdominal wall at the level of and medial to the anterior superior spine. The ureter is not stitched to the peritoneum or fascia but is fastened to the skin.

Ligation of ureter. A fourth possibility in the care of resected ureter is ligation. If previous urologic studies have shown good function of both kidneys without infection, ligation is probably the quickest and easiest procedure, although the chance must be taken that aseptic necrosis will follow ligation. Barney⁴ in 1912 demonstrated experimentally that not all ligated ureters result in an aseptic necrosis. Hepler⁵ in 1940 found that 3 per cent of patients so treated died, 24 per cent developed urinary fistulas, and 15 per cent ultimately had to have nephrectomy. Peacock⁶ in 1941 reported a series of 8 patients so

duration of symptoms was 5.1 years. As shown by Table 1, 157 patients (60 per cent) presented

at operation no biliary disease other than gallstones. Their histories reveal that symptoms were present for as long as thirty-nine years, with the average period 4.6 years. It is significant that 34 per cent of the patients had symptoms for more than five years and 15 per cent for more than ten years.

One hundred and three patients (40 per cent) had one or more complications at operation, including acute cholecystitis, acute pancreatitis, cholelithiasis and carcinoma of the gall bladder (Table 2); of these, 6 had more than one complica-

tion and are therefore listed twice. Whereas the average duration in the cases without complications was 4.6 years, it was 6.7 years in the cases with complications. Generally speaking, the longer the duration of symptoms of gallstones, the greater was the probability of complications. The interesting fact is that of this series 33 per cent had symptoms for less than one year before operation and 47 per cent for less than three years. Sixty-nine patients (27 per cent) had acute cholecystitis, including empyema, gangrene and acute free perforation of the gall bladder (Table 3). The

toms for five or more years, 33 per cent had had symptoms for less than one year. Six had no symptoms before the acute attack precipitating operation. These figures correspond with those in an analysis by Glenn,⁷ according to which 7 per cent of a series of patients had complications at the time of the initial symptoms and approximately 40 per cent had had symptoms for less than one year. It is thus apparent that acute cholecystitis may develop either early or late during the course of gallstones.

Although there is no general agreement concerning the pathogenesis of acute pancreatitis, a significant and fairly constant finding is its association with gallstones.⁸ Calculi have been reported in 70 to 81 per cent of cases of acute pancreatitis,⁹ which is therefore usually considered a complication of gallstones. In the present series 10 patients (4 per cent) had acute pancreatitis (Table 4). These cases,

according to Abell's¹⁰ classification, included acute pancreatic edema, acute pancreatic necrosis and acute pancreatitis with hemorrhage. Five patients in this group had symptoms for less than one year before operation, 2 having acute pancreatitis with their first attack of biliary distress; 3 had symptoms for two years and 2 for thirteen and seventeen years, respectively. The average duration was 3.9 years. Acute pancreatitis was often an early complication than a late sequelae of gallstones. Thirty-two patients (12 per cent) had stones in the common duct (Table 5). The average duration

of symptoms was 5.6 years, which with the exception of the cases of carcinoma of the gall bladder was the longest for those with complications. The duration period varied from less than one year to twenty years, except for 1 case with symptoms for forty years. Ten patients (31 per cent) were operated on before the end of twelve months; in fact, 3 were found to have stones in the common duct at operation following the first attack of colic. Fifty

patients were operated on after having had symptoms practically the same interval as in the cases without complications. Although 35 per cent of the average duration of symptoms was 4.9 years, which is practically the same interval as in the cases without complications. Although 35 per cent of the

blocked ureter, and an intravenous pyelogram should be done in this event to prove or disprove the diagnosis. The following case is illustrative.

CASE 8. M. L., a 49-year-old nulliparous woman, had a total hysterectomy for fibroids. A daily temperature of 102°F. was attributed to a draining ear until she complained of costovertebral angle tenderness. An intravenous pyelogram demonstrated that the left ureter was blocked 5 cm. from the bladder. The patient's condition improved until the 20th postoperative day, when she lapsed into a coma and died. Autopsy showed that the left ureter was tied off by a catgut ligature; that was also a massive cerebral hemorrhage.

SUMMARY AND CONCLUSIONS

Eight cases of ureteral injury among 760 hysterectomies performed at the Massachusetts General Hospital are discussed.
